174 FERC ¶ 61,126  
UNITED STATES OF AMERICA  
FEDERAL ENERGY REGULATORY COMMISSION

Before Commissioners: Richard Glick, Chairman;  
Neil Chatterjee, James P. Danly,  
Allison Clements, and Mark C. Christie.

Algonquin Gas Transmission, LLC  
Maritimes & Northeast Pipeline, LLC

Docket No. CP16-9-012

ORDER ESTABLISHING BRIEFING

(Issued February 18, 2021)

1. On September 24, 2020, Commission staff issued an order authorizing Algonquin Gas Transmission, LLC (Algonquin) and Maritimes & Northeast Pipeline, LLC (Maritimes) (together, Applicants) to place facilities associated with the Atlantic Bridge Project into service (Authorization Order).<sup>1</sup> On October 23, 2020, the Fore River Residents Against the Compressor Station (Fore River Residents), the City of Quincy, Massachusetts, Weymouth Councilor Rebecca Haugh, Michael Hayden, and Food and Water Watch (collectively Petitioners) filed a timely joint request for rehearing of the Authorization Order. Since issuance of the Authorization Order the Commission has also received numerous other pleadings expressing safety concerns regarding the operation of the project.

2. We believe that the concerns raised regarding the operation of the project warrant further consideration by the Commission and set the matter for paper briefing to address the questions listed below. Initial briefs will be due 45 days from the date of this order. Reply briefs will be due 30 days thereafter. The facilities placed in service pursuant to the Authorization Order may remain in service while the Commission considers the issues raised here. The Commission asks for briefing on the following matters:

- In light of the concerns expressed regarding public safety, is it consistent with the Commission's responsibilities under the Natural Gas Act (NGA) to allow the Weymouth Compressor Station to enter and remain in service?

---

<sup>1</sup> *Algonquin Gas Transmission, LLC*, Docket No. CP16-9-000, at 1 (Sept. 24, 2020) (delegated order) (Authorization Order).

- Should the Commission reconsider the current operation of the Weymouth Compressor Station in light of any changed circumstances since the project was authorized? For example, are there changes in the Weymouth Compressor Station's projected air emissions impacts or public safety impacts the Commission should consider? We encourage parties to address how any such changes affect the surrounding communities, including environmental justice communities.
- Are there any additional mitigation measures the Commission should impose in response to air emissions or public safety concerns?
- What would the consequences be if the Commission were to stay or reverse the Authorization Order?

The Commission orders:

Briefing procedures are hereby established, as discussed in the body of this order. Initial briefs are due 45 days from the date of this order and reply briefs are due 30 days thereafter.

By the Commission. Commissioner Danly is dissenting with a separate statement attached.  
Commissioner Christie is dissenting with a separate statement attached.

( S E A L )

Kimberly D. Bose,  
Secretary.

UNITED STATES OF AMERICA  
FEDERAL ENERGY REGULATORY COMMISSION

Algonquin Gas Transmission, LLC  
Maritimes & Northeast Pipeline, LLC

Docket No. CP16-9-012

(Issued February 18, 2021)

DANLY, Commissioner, *dissenting*:

1. I dissent in full from the majority's "Order Establishing Briefing" in *Algonquin Gas Transmission, LLC* Docket No. CP16-9-012. This order is both contrary to law and bad policy. Before I explain my reasoning, a complete recitation of the background facts is necessary.

**I. Background**

2. Over four years ago, on January 25, 2017, the Commission issued Algonquin Gas Transmission, LLC (Algonquin) a certificate authorizing the construction and operation of the Weymouth Compressor Station as part of the Atlantic Bridge Project.<sup>1</sup> The Commission found the project to be in the public convenience and necessity after considering the project need and the environmental effects of the project, including the effects that constructing and operating the Weymouth Compressor Station would have on safety, air quality, and environmental justice communities.<sup>2</sup> The Certificate Order found that the Weymouth Compressor Station would not result in a significant increase in risk to the nearby public "[b]ased on Algonquin's commitment to comply with [Pipeline and Hazardous Materials Safety Administration (PHMSA)] requirements."<sup>3</sup> In addition, the Commission's Environmental Assessment (EA) estimated the fugitive emissions (including blowdowns) at the Weymouth Compressor Station, compared the emissions to

---

<sup>1</sup> *Algonquin Gas Transmission, LLC*, 158 FERC ¶ 61,061 (2017) (Certificate Order). Chairman Bay, Commissioner LaFleur, and Commissioner Honorable unanimously approved the certificate.

<sup>2</sup> See *id.* PP 225-238 (safety), *id.* PP 194-216 (air quality), *id.* PP 185-189 (environmental justice). The Certificate Order also addressed specific air quality and health effects from blowdowns. See *id.* PP 198, 223

<sup>3</sup> *Id.* P 226.

a past health risk assessment performed on a similar facility, and found that the health risks from operating the compressor station would not be significant.<sup>4</sup>

3. In December 2018, the U.S. Court of Appeals for the D.C. Circuit upheld the Certificate Order, including the Commission's assessment of impacts on public safety and environmental justice.<sup>5</sup>

4. On November 27, 2019, Commission staff authorized Algonquin to commence construction of the Weymouth Compressor Station after confirming that Algonquin had received all federal authorizations relevant to the approved activities. Those federal authorizations included its Air Quality Plan approved by the Massachusetts Department of Environmental Protection (Massachusetts DEP).

5. Late summer last year, Algonquin began testing its compressor station facilities as required by PHMSA.<sup>6</sup> Section 192.503 of PHMSA's regulations prohibits any person from operating a new segment of pipeline until "(1) [i]t has been tested in accordance with this subpart and § 192.619 to substantiate the maximum allowable operating pressure; and (2) [e]ach potentially hazardous leak has been located and eliminated."<sup>7</sup> Further, section 192.503 requires the test medium to be "liquid, air, natural gas, or inert gas."<sup>8</sup>

6. On September 11, 2020, during Algonquin's testing of equipment, a gasket failed, triggering the manual activation of its emergency shutdown system. Section 192.167 of the PHMSA's regulations requires compressor stations to have emergency shutdown systems that blow down the station piping.<sup>9</sup> Consequently, Algonquin's emergency shutdown system blew down natural gas, releasing 169,000 standard cubic feet (scf) of natural gas and 35 pounds (lbs) (or 0.0175 tons<sup>10</sup>) of Volatile Organic Compounds (VOCs), which is approximately 0.19 percent of the estimated 9.0 tons of annual fugitive

<sup>10</sup> One ton equals 2,000 lbs.

VOCs evaluated by the EA.<sup>11</sup> Thereafter, Algonquin continued testing and calibrating activities.<sup>12</sup> The record does not show Massachusetts DEP initiating a compliance action.

7. On September 16, 2020, Algonquin requested authorization to place the Weymouth Compressor Station into service pursuant to Environmental Condition 10 of the Certificate Order. Environmental Condition 10 requires Algonquin to “receive written authorization from the Director of OEP before commencing service on each discrete facility of the Project” and provided that “[s]uch authorization will only be granted following a determination that rehabilitation and restoration of the right-of-way and other areas affected by the Project are proceeding satisfactorily.”<sup>13</sup>

8. On September 24, 2020, Commission staff authorized Algonquin to place its Weymouth Compressor Station into service, finding that “Algonquin and Maritimes [had] adequately stabilized areas disturbed by construction and that restoration is proceeding satisfactorily.”<sup>14</sup>

9. On September 30, 2020, the Weymouth Compressor Station experienced an unplanned emergency shutdown, releasing approximately 195,000 scf of natural gas, including 27 lbs (or 0.0135 tons) of VOCs, which is approximately 0.15 percent of the estimated 9.0 tons of annual fugitive VOCs evaluated by the EA. The cause of the unplanned shutdown was unknown. That same day, Algonquin voluntarily shut in its system.<sup>15</sup> The record does not show Massachusetts DEP initiating a compliance action.

10. On October 1, 2020, as amended on October 30, 2020, PHMSA issued a Corrective Action Order directing Algonquin to not operate the compressor station until authorized to do so, develop a Restart Plan for approval, and complete a root cause failure analysis.<sup>16</sup>

---

<sup>11</sup> EA at 2-95, tbl. 2.7.4-3.

<sup>12</sup> Algonquin October 7, 2020 Weekly Status Report No. 177 for the Reporting Period Ending September 11, 2020 at 3.

<sup>13</sup> Certificate Order, 158 FERC ¶ 61,061 at Appendix B, Environmental Condition 10.

<sup>14</sup> Commission Staff September 24, 2020 Letter Order Authorizing Commencement of Service at 1 (Authorization Order).

<sup>15</sup> Algonquin October 7, 2020 Weekly Status Report No. 180 for the Reporting Period Ending October 2, 2020 at 2.

<sup>16</sup> PHMSA, Corrective Action Order (Oct. 1, 2020),

11. On October 23, 2020, Petitioners<sup>17</sup> filed a timely request for rehearing of Commission staff's September 24, 2020 Letter. First, they argued that the Commission "failed to complete a situational assessment and strategic responses for public safety and environmental impacts associated with incidents involving natural gas infrastructure."<sup>18</sup> Second, they argued "[t]he unplanned emergency shutdowns and COVID-19 pandemic . . . rise to the level of a change in core circumstances" requiring the Commission to reopen the record under Rule 716 of the Commission's Rules of Practice and Procedure.<sup>19</sup> Petitioners did not challenge Commission staff's finding that restoration and rehabilitation was proceeding satisfactorily.

12. On November 23, 2020, the Commission issued a notice denying Petitioners' rehearing request by operation of law.

13. On November 25, 2020, PHMSA approved Algonquin's Restart Plan and authorized Algonquin to return the compressor station facilities to a pressure not exceeding 80 percent of full operating pressure.<sup>20</sup>

14. On January 22, 2021, PHMSA approved the temporary operation of the Weymouth Compressor Station at full pressure, stating "PHMSA has reviewed the [root cause failure analysis] and the data submitted on [Algonquin's] preventative and mitigative measures performed and based on our technical review, it is our determination to allow the temporary removal of the pressure restriction."<sup>21</sup>

<sup>21</sup> PHMSA, Letter Approving Enbridge Allowing Temporary Removal of Pressure

15. On January 25, 2021, Algonquin placed the Weymouth Compressor Station into service.<sup>22</sup>

16. Now on February 18, 2021—over four years after the Commission issued the Certificate Order authorizing the operation of the Weymouth Compressor Station, nearly four months after Petitioners’ timely rehearing request, after PHMSA has authorized Algonquin to resume operating the Weymouth Compressor Station at full pressure, and without any indication that Algonquin is out of compliance with its air permit—the Commission is issuing this “Order Establishing Briefing.”

## **II. The Order is an Attempt to Revisit the Certificate Proceeding and is Contrary to Law**

### **A. This Order is an Attempt to Revisit the Certificate Order**

17. It is somewhat difficult to make sense of this order. On its face, it bears the benign-sounding title “Order Establishing Briefing.” Those sorts of orders are issued now and again; they are procedural and, one would think, warrant little scrutiny. But briefing for what? The Certificate Order and the Authorization Order are both final—the Certificate Order was issued more than four years ago, and as for the Authorization Order, rehearing was denied by operation of law and the opportunity to appeal lapsed without a petition for review. Both of those proceedings appear to be irretrievably final. And, in fact, this order is *neither* of those proceedings. The Commission has assigned a new sub-docket number, -012, to distinguish it from the rehearing proceeding.<sup>23</sup> Confusion is justified as to what exactly is at issue since the Order Establishing Briefing cites to pleadings filed in the rehearing sub-docket.

18. Procedural oddities aside, this order does not look like other orders, by which I mean that those few people who spend a large amount of their time reading Commission orders will enjoy the familiarity of the caption and paragraph format but will be left with vague unease as they notice that the order is missing some fairly standard contents. It has no background section. It offers no basis in law for the Commission’s action. It provides no explanation as to what it is trying to achieve other than a vague promise of the “further

---

Restriction at Weymouth Compressor Station at 1 (Jan. 22, 2021), [https://www.phmsa.dot.gov/sites/phmsa.dot.gov/files/2021-01/12020014CAO\\_Region%20Response%20to%20Corrective%20Action%20Item%205\\_01222021.pdf](https://www.phmsa.dot.gov/sites/phmsa.dot.gov/files/2021-01/12020014CAO_Region%20Response%20to%20Corrective%20Action%20Item%205_01222021.pdf).

<sup>22</sup> Algonquin January 25, 2021 Notice of Commencement of Service.

<sup>23</sup> With a new docket number may come a new intervention period. Every pipeline company, shipper, and pipeline investor should consider intervening in this “new” proceeding.

consideration” of something.<sup>24</sup> In fact, in the last 10 years, the Commission has never issued an order captioned “Order Establishing Briefing” and to the extent that free-standing briefing orders have issued during that time, they have issued following remand from appellate courts, or to address issues not resolved in settlement, motions for interlocutory appeal, and investigations into the justness and reasonableness of rates.<sup>25</sup>

19. So what exactly does this order purport to do? It states that staff authorized Algonquin to place the Weymouth Compressor Station into service and it mentions that a timely rehearing request and other pleadings were filed. Then it states that the Commission “believe[s] that the concerns raised regarding the operation of the project warrant further consideration by the Commission and set[s] the matter for paper briefing to address” a series of appended questions.<sup>26</sup> By its plain language, the order requests

---

<sup>24</sup> This formulation, “further consideration,” is particularly unfortunate and perhaps even provocative in an order issued in a closed docket following the D.C. Circuit’s issuance of *Allegheny Defense Project v. FERC*, 964 F.3d 1 (D.C. Cir. 2020) (en banc).

<sup>25</sup> See, e.g., *Am. Elec. Power Serv. Corp. v. Midcontinent Indep. Sys. information on a set of discrete topics for the Commission’s “further consideration.” To what end? Among other things, the questions ask, rather ominously, (1) whether the Commission “should allow the Weymouth Compressor Station to enter and remain in service”; (2) whether the Commission should “reconsider” the current operation of the compression station; (3) whether the Commission “should consider” changes in air emissions or public safety impacts; (4) whether there are any “additional mitigation measures” the Commission should “impose” (presumably by means of revising Environmental Condition 10 of the Certificate Order); and (5) what would happen if the Commission were to “stay or reverse” the Authorization Order.

20. It would appear that the Commission is collecting comments in order to determine whether it should re-litigate the Certificate Order absent a breach or violation of the certificate terms and conditions. Though the majority may be laboring under the impression that this Order Establishing Briefing is no more than a late attempt to grant a (now denied and final, non-appealable) rehearing request sought following the Authorization Order, the Order asks questions that go directly the Certificate Order only. Only by re-litigating the Certificate Order and modifying Environmental Condition 10 of the Certificate Order can the Commission “reconsider the current operation of the Weymouth Compressor Station,” consider “changes in . . . projected air emissions or public safety impacts,” “impose” “additional mitigation measures,” or “stay or reverse the Authorization Order.” Moreover, none of the questions address the basis for the Authorization Order—whether the rehabilitation and restoration of lands affected by project construction were proceeding satisfactorily.

### **B. The Order Establishing Briefing is Contrary to Law**

21. This Order is legally infirm because the action is simply beyond the Commission’s authority. Even if it were not *ultra vires*, the Commission has fallen short of its Administrative Procedure Act (APA) obligations by failing to explain why it departs from the Commission’s rules and policies.

22. There is a good reason for why the Commission fails to cite legal authority for today’s order—“[t]he Commission has already approved the [c]ertificate, and there is nothing in the law that allows us to revisit that decision.”<sup>27</sup> Just so. The current Commission may believe that the Commission, voting unanimously, acted improvidently in early 2017. They may believe that circumstances have changed.<sup>28</sup> They may believe

---

Establishing Briefing).

<sup>27</sup> Commissioner (now Chairman) Glick, Comments at Open Meeting at 29 (Jan. 19, 2021).

<sup>28</sup> Circumstances, however, have not changed and additional briefing on this matter is not needed to make this finding. The Certificate Order found that there were no

that the parties seeking rehearing were completely correct and that rehearing should have been granted. They may be right.<sup>29</sup> Regardless, there is no basis in law to re-examine final orders.

23. The Commission, as a mere creature of statute, can only act pursuant to law by which Congress had delegated its authority.<sup>30</sup> Although courts afford agencies great discretion to establish the procedures by which they conduct their business, that business, however fashioned, must be conducted within the bounds of that delegation.<sup>31</sup>

24. Nowhere does NGA section 7 authorize the Commission to unilaterally revisit final certificate orders or establish briefing schedules to inform such actions. Quite the contrary. NGA section 7(e) states: “a certificate shall be issued . . . if it is found that the applicant is able and willing properly to do the acts . . .”<sup>32</sup> and “[t]he Commission shall have the power to attach to the issuance of the certificate and to the exercise of the rights granted thereunder such reasonable terms and conditions . . .”<sup>33</sup> So conditioned, the

---

significant impacts on safety because Algonquin would comply with PHMSA regulations. Certificate Order, 158 FERC ¶ 61,061 at P 226. Algonquin has done so. *See supra* PP 5-6, 9-10, 13-14. Further, the Commission considered blowdown events, such as those that occurred in September, and found they would not have significant effects on air quality and health. EA at 2-98. And moreover, the amount of VOCs released by the events amounted to only 0.34 percent of the estimated blowdown emissions from the Weymouth Compressor Station in the EA. *See supra* PP 6, 9.

<sup>29</sup> This is unlikely. Every subject raised in the rehearing requests was fully litigated at various stages of the underlying proceedings. *See* Appendix.

<sup>30</sup> *Bowen v. Georgetown Univ. Hosp.*, 488 U.S. 204, 208 (1988) (“It is axiomatic that an administrative agency’s power to promulgate legislative regulations is limited to the authority delegated by Congress.”); *accord, e.g., Atl. City Elec Co. v. FERC*, 295 F.3d 1 (D.C. Cir. 2002) (“As a federal agency, FERC is a ‘creature of statute,’ having ‘no constitutional or common law existence or authority, but *only* those authorities conferred upon it by Congress.’”) (quoting *Michigan v. EPA*, 268 F.3d 1075, 1081 (D.C. Cir. 2001)) (emphasis in original).

<sup>31</sup> For example, the Commission established a tolling procedure for rehearing requests in which the D.C. Circuit found was contrary to the Natural Gas Act (NGA). *See Allegheny Def. Project v. FERC*, 964 F.3d 1.

<sup>32</sup> 15 U.S.C. § 717f(e).

<sup>33</sup> *Id.* *See also Trunkline LNG Co.*, 22 FERC ¶ 63,028, at 65,135-39 (1983) (Chief Administrative Law Judge Recommended Decision).

Commission's regulations require the pipeline to then accept the certificate order.<sup>34</sup> In sum, the Commission's power is to grant, with conditions, a certificate of public convenience and necessity and to enforce the certificate. Absent a violation of those conditions, once the certificate issues and becomes final, the Commission has never revisited a certificate order and has in fact always doubted its ability to do so.<sup>35</sup>

25. Many are quick to turn to NGA section 16 when all else has failed, but it is often freighted with more weight than it can bear. Section 16 does not represent an independent grant of authority: "[t]he Commission shall have power to perform any and all acts, and to prescribe, issue, make, amend, and rescind such orders, rules, and regulations as it may find necessary or appropriate to carry out the provisions of this chapter."<sup>36</sup> This does not create new powers under the NGA or obviate NGA section 7(e), which limits the Commission's authority over a certificate to the certificate's conditions.<sup>37</sup> Moreover, like its counterpart in FPA section 309, the use of NGA

---

<sup>34</sup> 18 C.F.R. § 157.20(a) (2020) ("The certificate shall be void and without force or effect unless accepted in writing by applicant within 30 days from the issue date of the order issuing such certificate."). *Cf.* 16 U.S.C. § 799 ("Each such license shall be conditioned upon acceptance by the licensee of all of the terms and conditions of this chapter and such further conditions, if any, as the Commission shall prescribe in conformity with this chapter, which said terms and conditions and the acceptance thereof shall be expressed in said license."); *Clifton Power Corp. v. FERC*, 88 F.3d 1258, 1261 (D.C. Cir. 1996) (concluding that the Commission erred in finding the license required the licensee to operate the project in a run-of-river mode because the license order did not contain an explicit condition requiring the licensee to operate run-of-river).

<sup>35</sup> *Trunkline LNG Co.*, 22 FERC ¶ 61,245, at 61,442 (1983). In *Trunkline*, the Commission declined to address whether it had the authority to revisit a certificate. However, to the extent the Commission has the authority, the Commission stated that action, "would be an extraordinary step and would, in our judgment, require a compelling showing of a fundamental shift of a long-term nature in the basic premises on which the certificate was issued." *Id.* at 61,442. The Commission also stated "because the project had previously been approved by the Commission and funds committed based on that approval, the Commission would be obligated to revoke or modify the certificate in a manner that would leave investors in the project in substantially the same position they would have been had the Commission not revoked or modified the certificate." *Id.* at 61,442 n.5. The record shows no fundamental shift, and the Order Establishing Briefing asks no questions on how to leave investors in substantially the same position they would have been.

<sup>36</sup> 15 U.S.C. § 717o.

<sup>37</sup> *Fla. Gas Transmission Co. v. FERC*, 604 F.3d 636, 647 (D.C. Cir. 2010)

section 16 must be “consistent with the authority delegated to it by Congress.”<sup>38</sup> But the order here does not do so because it flies in the face of the statutory process for rendering final orders subject to judicial review.

26. No other law, regulation, or policy can be relied upon to revisit a certificate. Rule 716, which allows the Commission to reopen the record in certain proceedings,<sup>39</sup> explicitly applies only to initial or revised initial decisions and, moreover, *does not apply* to final, unappealable orders.<sup>40</sup> And even if there were another source of authority, the Commission has failed to explain how the exercise of that authority in this proceeding can be squared with the Commission’s longstanding practice of leaving final,

---

(“[W]hile section 16 gives the Commission ancillary jurisdiction to carry out the statute’s other provisions, it does not confer additional jurisdiction . . . otherwise outside the Commission’s jurisdiction.”) (citing *Pub. Serv. Comm’n of N.Y. v. FERC*, 866 F.2d 487, 491-92 (D.C. Cir. 1989)).

<sup>38</sup> *Verso Corp. v. FERC*, 898 F.3d 1, 7 (D.C. Cir. 2018) (citing *Xcel Energy Servs. Inc. v. FERC*, 815 F.3d 947, 952 (D.C. Cir. 2016)); *accord id.* at 10 (“Section 309 accordingly permits FERC to advance remedies not expressly provided by the FPA, *as long as they are consistent with the Act.*”) (emphasis added) (citing *TNA Merch. Projects, Inc. v. FERC*, 857 F.3d 354, 359 (D.C. Cir. 2017) (citing *Niagara Mohawk Power Corp. v. Fed. Power Comm’n*, 379 F.2d 153, 158 (D.C. Cir. 1967))).

<sup>39</sup> 18 C.F.R. § 385.716 (2020). “Initial decision” is “any decision rendered by a presiding officer in accordance with Rule 208”—meaning a decision rendered by the Administrative Law Judges, not the Commission. *Id.* § 385.702. The Commission has previously applied Rule 716 to Commission orders despite the Commission’s regulations to the contrary. *See Panhandle E. Pipe Line Co. v. FERC*, 613 F.2d 1120, 1135 (D.C. Cir. 1979) (“[W]e do not believe the Commission should have authority to play fast and loose with its own regulations. It has become axiomatic that an agency is bound by its own regulations.”). To my knowledge, the Commission has never reopened a record of a final order that was affirmed on appeal. Nor can the majority square reopening the record of the Authorization Order with its long-standing policy to reopen only where there is “a change in the core circumstance that goes to the very of the case,” *CSM Midland, Inc.*, 56 FERC ¶ 61,177, at 61,624 (1991), as the safety and air emissions are entirely unrelated to the issuance of the Authorization Order. Similarly, the majority has not explained its departure from its long-standing policy.

<sup>40</sup> *See N. Nat. Gas Co.*, 113 FERC ¶ 61,060, at 61,170 (2005); *Old Dominion Elec. Coop.*, 105 FERC ¶ 61,094, at 61,485 (2003).

unappealable orders undisturbed. Failure to set forth that explanation, in the face of so long a practice, is necessarily a violation of the APA.<sup>41</sup>

### III. The Order is Bad Policy

27. On top of being unlawful, the Order is bad policy. Issuing an order that appears to revisit final, unappealable certificate orders impairs regulatory certainty and arrogates to the Commission authority it does not have.

28. Regulatory certainty, of which finality is a large part, is absolutely critical to achieving the goals of the NGA. “[W]ithout the sanctity of certificates granted under Sections 3 and 7 of the Natural Gas Act, there would be no private financing, and without private financing, there would be no projects.”<sup>42</sup> Further, “the revocation or adverse modification of a certificate or authorization . . . when the certificate or authorization forms the basis of project financing would be a clear violation of the basic constitutional principles of due process.”<sup>43</sup>

29. Worse still, the Order Establishing Briefing impairs the finality normally enjoyed by certificate holders, based on issues well outside our jurisdiction. The Order asks: whether the Commission should revisit the Certificate Order on the basis of pipeline operational safety and air emissions. Reading this, one would presume that Algonquin is not in compliance with pipeline safety and air emission requirements and the Commission has the authority and expertise to address the non-compliance. Neither of those presumptions, however, is correct.

30. First, as I note above, PHMSA and Massachusetts DEP appear satisfied that Algonquin is complying with their regulations and requirements. Nearly one month ago, PHMSA authorized Algonquin to resume operating the Weymouth Compressor Station at

---

<sup>41</sup> See *FCC v. Fox Television Stations, Inc.*, 556 U.S. 502, 515 (2009) (“[T]he requirement that an agency provide reasoned explanation for its action would ordinarily demand that it display awareness that it *is* changing position.”) (emphasis in original); *id.* (“[A]n agency may not . . . depart from a prior policy *sub silentio* or simply disregard rules that are still on the books.”); *New England Power Generators Ass’n, Inc. v. FERC*, 881 F.3d 202, 211 (D.C. Cir. 2018) (finding “that FERC did not engage in the reasoned decisionmaking required by the Administrative Procedure Act” because it “failed to respond to the substantial arguments put forward by Petitioners and *failed to square its decision with its past precedent*”) (emphasis added).

<sup>42</sup> *Trunkline LNG Co.*, 22 FERC ¶ 63,028 at 65,139.

<sup>43</sup> *Id.*

full pressure.<sup>44</sup> Massachusetts DEP approved the Air Quality Plan for the Weymouth Compressor Station, finding it is in compliance with the Air Pollution Control regulations and current air pollution control engineering practice.<sup>45</sup> The record does not show Massachusetts DEP initiating a compliance action.

31. Second, Congress expressly delegated to the Secretary of the Department of Transportation the authority to regulate pipeline safety<sup>46</sup> and to the U.S. Environmental Protection Agency (EPA) the authority to regulate air emissions.<sup>47</sup> The Commission's long-standing practice is to rely on PHMSA to regulate pipeline safety and the EPA, or its state delegated agency, to regulate air emissions.<sup>48</sup> It is baffling on what factual basis the Commission could modify the Certificate Order and what additional measures the Commission could impose that PHMSA and Massachusetts DEP have not considered and would not interfere with their approvals.

---

<sup>44</sup> See *supra* P 14.

<sup>45</sup> Massachusetts DEP, Air Quality Plan Approval at 2 (Aug. 26, 2019), <https://www.mass.gov/doc/air-quality-plan-approval-august-2019/download>. Massachusetts affirmed the plan on September 29, 2020. Massachusetts DEP, Final BACT Determination for Weymouth Compressor Station at 1, <https://www.mass.gov/doc/final-bact-determination-september-29-2020/download>.

<sup>46</sup> See 49 U.S.C. § 60102(a)(2) (2018) (“The Secretary shall prescribe minimum safety standards for pipeline transportation and for pipeline facilities.”); see also FERC, Natural Gas Safety and Inspections, <https://www.ferc.gov/industries-data/natural-gas/safety-and-inspections> (“[o]nce Natural Gas pipeline projects become operational, safety is regulated, monitored, and enforced by the Department of Transportation”); FERC, Strategic Plan FY2018-2021 at vii, <https://www.ferc.gov/sites/default/files/2020-04/FY-2018-FY-2022-strat-plan.pdf> (lists “[r]esponsibility for pipeline safety” under the heading “What FERC does not do”).

<sup>47</sup> See *Wyoming v. U.S. Dep’t of Interior*, 2020 WL 7641067 \*9 (Oct. 8, 2020) (“The rub here, however, is whether the Rule, or at least certain provisions of the Rule, was promulgated *for the prevention of waste* or instead for the *protection of air quality*, which is expressly within the ‘substantive field’ of the EPA and States pursuant to the Clean Air Act.”) (emphasis in original).

<sup>48</sup> See *Town of Weymouth*, No. 17-1135, 2018 WL 6921213 at \*1 (“although the challengers argue that FERC impermissibly relied on the pipeline companies’ assertions that they would comply with certain federal safety regulations, FERC was entitled, ‘[a]bsent evidence to the contrary,’ to ‘assume . . . that [the companies] will exercise good faith.’ *Murray Energy Corp. v. FERC*, 629 F.3d 231, 240 (D.C. Cir. 2011).”).

32. Intended or not, the message from this order is clear: even if a pipeline has its certificate, a court upholds that certificate, and that pipeline is in compliance, the Commission can now find a way to modify, or even possibly revoke, the certificate. This order requires Algonquin to relitigate the Certificate Order affirmed over three years ago. Algonquin has now been aggrieved.<sup>49</sup> This order threatens the certainty of the certificate upon which the pipeline's business is founded, disregards the principles of final judgement upon which all litigants rely, and violates the specific statutory procedures devised by Congress to render and challenge final orders. The order manufactures what is essentially an end-run around the statutory process for rehearing and judicial review that is far more dangerous and disruptive than the Commission's past abuse of tolling orders,<sup>50</sup> because tolling orders only delayed the final resolution of cases, but did not constitute surprise attacks on long-final orders. Algonquin should appeal immediately.

For these reasons, I respectfully dissent.

## Appendix

### FERC Process

- On January 25, 2017, the Commission issued a Certificate Order to Algonquin, considering the safety risk of the compressor station, the air quality and health impacts of blowdowns, and impacts on environmental justice communities near the compressor station. *See Algonquin Gas Transmission, LLC*, 158 FERC ¶ 61,061 (2017).
- On December 13, 2017, the Commission denied rehearing after considering the safety risks of the Weymouth Compressor Station (PP 27-28, 32, 134-139), the effects of blowdowns (P 132), and environmental justice (PP 91-99). *See Algonquin Gas Transmission, LLC*, 161 FERC ¶ 61,255 (2017).
- On December 27, 2018, the U.S. Court of Appeals for the D.C. Circuit affirmed the Commission's Certificate Order, including its consideration of impacts on safety and environmental justice. *Town of Weymouth, Massachusetts*, No. 17-1135, 2018 WL 6921213 (D.C. Cir. Dec. 27, 2018) (unpublished opinion).

### Massachusetts DEP Air Quality Plan Approval

- In March 2017, Massachusetts DEP issued a proposed Air Quality Plan Approval, determining that the Massachusetts Environmental Justice Policy does not apply because the anticipated emissions would not exceed emission thresholds. *See* Massachusetts DEP, Air Quality Proposed Plan Approval (Mar. 30, 2017), <https://www.mass.gov/doc/proposed-air-quality-plan-approval-march-2017/download>.
- In the spring of 2017, Massachusetts DEP held a public comment period on the proposed Air Quality Plan Approval. *See* Massachusetts DEP Algonquin Natural Gas Compressor Station, Weymouth, <https://www.mass.gov/service-details/algonquin-natural-gas-compressor-station-weymouth>.
- In July 2017, Governor Baker directed Massachusetts DEP and the Massachusetts Department of Public Health to perform a comprehensive health impact assessment. *See id.*
- In January 2019, Massachusetts DEP and the Massachusetts Department of Health issued the *Health Impact Assessment of a Proposed Natural Gas Compressor Station in Weymouth*. The assessment considered health and environmental justice

impacts of the Weymouth Compressor Station. *See* Massachusetts Department of Health et al., *Health Impact Assessment of a Proposed Natural Gas Compressor Station in Weymouth*, MA (January 2019), [http://foreriverhia.wpengine.com/wp-content/uploads/2019/01/Final-Report\\_20190104.pdf](http://foreriverhia.wpengine.com/wp-content/uploads/2019/01/Final-Report_20190104.pdf).

- On January 11, 2019, Massachusetts DEP issued a Non-Major Comprehensive Air Quality Plan Approval to Algonquin for its construction and operation of the Weymouth Compressor Station. *See* Massachusetts DEP, Air Quality Plan Approval (January 11, 2019).
- In May and June 2019, an adjudicatory hearing was held on six appeals of Massachusetts DEP's approval. *See* Massachusetts DEP Algonquin Natural Gas Compressor Station, Weymouth, <https://www.mass.gov/service-details/algonquin-natural-gas-compressor-station-weymouth>.
- On August 26, 2019, Massachusetts DEP issued a Non-Major Comprehensive Air Quality Plan Approval, which incorporated conditions required by the final decisions resulting from the adjudicatory hearing and found that Massachusetts Environmental Justice Policy does not apply because the anticipated emissions would not exceed emission thresholds. Massachusetts DEP, Air Quality Plan Approval (Aug. 26, 2019), <https://www.mass.gov/doc/air-quality-plan-approval-august-2019/download>.
- On June 3, 2020, the U.S. Court of Appeals for the First Circuit affirmed in part Massachusetts DEP's Air Quality Plan Approval, including its assessment of environmental justice. *See Town of Weymouth, Massachusetts v. Mass. Dep't of Environmental Protection*, 961 F.3d 34, 54-55 (1st Cir. 2020), *amended*, 973 F.3d 143 (1st Cir. 2020).

UNITED STATES OF AMERICA  
FEDERAL ENERGY REGULATORY COMMISSION

Algonquin Gas Transmission, LLC  
Maritimes & Northeast Pipeline, LLC

Docket No. CP16-9-012

(Issued February 18, 2021)

CHRISTIE, Commissioner, *dissenting*:

1. What the majority does in this order is inconsistent with the purpose and principle behind a future-looking review of certification applications. Today, the Commission makes a foray into retroactively changing the rules long after the fact: long after construction was begun and long after investors committed significant funds, as described below, to a project. Today's capricious action violates the most basic standards of regulatory due process and regulatory finality, both of which are absolutely necessary to balance appropriate regulatory protections for people who live in geographic proximity to infrastructure projects with regulatory certainty for those who are building and financing needed infrastructure to provide vital services to consumers and create jobs for Americans.

2. On January 25, 2017 – more than four years ago – this Commission authorized Applicants to construct and operate certain pipeline and compression facilities in New York, Connecticut, and Massachusetts (Atlantic Bridge Project), and, in so doing, found that the “*public convenience and necessity require approval and certification of the Atlantic Bridge Project under section 7 of the NGA,*” subject to certain conditions.<sup>1</sup> In reliance on the issuance of that certificate of public convenience and necessity (CPCN), investors committed hundreds of millions of dollars to construct the project.<sup>2</sup> Construction took place and on September 24, 2020, Commission staff issued a delegated letter order authorizing the remaining facilities associated with the Atlantic Bridge

---

<sup>1</sup> *Algonquin Gas Transmission, LLC*, 158 FERC ¶ 61,061 at P 31 (Certificate Order) (emphasis added), *order on reh'g*, 161 FERC ¶ 61,255 (2017) (Certificate Rehearing Order), *aff'd sub nom., Town of Weymouth v. FERC*, No. 17-1135, 2018 WL 6921213, at \*1 (D.C. Cir. Dec. 27, 2018) (unpublished opinion).

<sup>2</sup> The Certificate Order states that, at the time of the applications, Applicants estimated the cost of the Atlantic Bridge Project to be \$451,791,440. Certificate Order at P 10 (footnote omitted).

Project be placed into service, including the Weymouth Compressor Station in Norfolk, Massachusetts, and the Maritimes Westbrook Metering and Regulator Station in Cumberland, Maine, and finding that “Algonquin and Maritimes have adequately stabilized areas disturbed by construction and that restoration is proceeding satisfactorily.”<sup>3</sup>

3. Now, four years after finding *public convenience and necessity require approval and certification of the Atlantic Bridge Project* and inviting investors to commit substantial funds to build it, and without recognizing the request for rehearing was denied by operation of law, the majority literally invites opponents of the project to re-litigate the core question of whether the project should even have been built. The majority’s order unquestionably raises the specter of shutting down this completed and functioning project even permanently, although it offers no discussion as to how it would do so under the law.

4. The majority’s decision is apparently – it is unclear – based on an alleged safety issue with a compressor station that is no longer under this Commission’s jurisdiction, but is rather under that of another federal agency.<sup>4</sup> The Certificate Rehearing Order states that the U.S. Department of Transportation’s Pipeline and Hazardous Materials Safety Administration (PHMSA) is the agency charged with developing safety regulations for the design and operation of natural gas pipeline facilities and enforces compliance with these regulations. To compound the Kafkaesque quality of the Commission’s action, PHMSA has already investigated and given the compressor facility a temporary green light to operate.<sup>5</sup>

---

<sup>3</sup> *Algonquin Gas Transmission, LLC*, Docket No. CP16-9-000, at 1 (Sep. 24, 2020) (delegated order) (Authorization Order). Subsequent to the Authorization Order, on October 23, 2020, the Fore River Residents Against the Compressor Station (Fore River Residents), the City of Quincy, Massachusetts, Weymouth Councilor Rebecca Haugh, Michael Hayden, and Food and Water Watch filed what was styled as request for rehearing of the Authorization Order.

<sup>4</sup> The Commission’s action *may* also be based on an argument in the request for rehearing that has already been denied by operation of law, that the Weymouth Compressor Station poses a threat to neighboring communities during the COVID-19 pandemic and represents a change in core circumstances that requires the Commission to re-open the record in this proceeding. Such an argument appears to be another attempt to re-open and re-litigate the original certificate proceeding with a goal of overturning that decision and shutting the project down permanently.

<sup>5</sup> See *In the Matter of Algonquin Gas Transmission, LLC*, Corrective Action Order, CPF No. 1-2020-014-CAO, Dep’t of Transp. (Oct. 2020) (prohibiting Algonquin from operating the Weymouth Compressor station following two unplanned emergency

5. Fairness and due process in the regulatory consideration of project certification applications means litigating all relevant issues during the original proceeding, providing for robust public participation, and then issuing a decision well-grounded in law and fact. Then out of fairness to all concerned, the regulatory body should stand behind its decision. Today's decision violates this basic standard.

6. Instead, today's order creates more questions than it answers and leaves uncertainty only in its wake. Nothing in today's order suggests that the Commission has not left open the possibility that it will shut down this project. As a result, today's order may, regrettably, impact investment in *all* infrastructure projects making them less appealing to engage in by those who normally seek to build the projects and harder to finance or, at the very least, more expensive to finance due to the increased risk created by this specter of uncertainty.

7. Mark Twain said the art of prophecy is very difficult, especially with respect to the future; however, I suspect that the use of the legal weapons of unending litigation and collateral attacks against infrastructure projects long after they have been approved, as is enabled by today's order, will not be limited to natural gas projects, even though they are today's primary target. Campaigns of unending legal warfare may well be used one day against other types of infrastructure projects, including those the majority may well want to promote.

For these reasons, I respectfully dissent.

## From Raina Rippel, Environmental Health Project Director

*Health Effects Associated with Chemical Emissions from NYS Natural Gas Compressor stations: 2008-2014* is a report on the chemical and particulate emissions of eighteen compressor stations in New York State (NYS), based on what companies are required to report to NY Department of Environmental Conservation (DEC) and National Emissions Inventory (NEI) of the U.S. Environmental Protection Agency (EPA). In addition, it presents the potential health effects of the 70 chemicals catalogued. The Report is aimed primarily at New York state and local governmental officials and administrators in order to raise their awareness of the size and scope of the air emissions generated by unconventional natural gas compressor stations. Many public officials are in positions to make decisions about siting compressor stations so that people who live nearby are relatively safe. EHP and IHE believe that the data provided in this Report should play a central role in that decision-making.

Secondarily, the Report is intended to inform communities, NGOs, and health care professionals about emissions from the eighteen compressor stations in NYS. It is not, however, designed to help quantify the risk of any particular community. Here's the reason why:

The presence of a chemical with disease-causing properties does not necessarily result in disease in any one individual. For instance, some chemicals are only harmful beyond a certain level of exposure (often referred to as a "dose"). Some are more likely to be harmful if exposure is repeated before the body has had the opportunity to clear the preceding exposure. Others are more likely to cause disease or symptoms in vulnerable populations. That said, some of the chemicals reported by the companies will likely produce health effects in individuals living, working or going to school near the compressor stations. (David Brown, ScD, EHP Toxicologist and Public Health Scientist)

There are important reasons, however, for communities, NGOs and health care professionals to make use of this report. These 18 compressor stations are the seventh largest "Point source" of air pollution in New York State, and emit a large array of chemicals, in conjunction with fine and ultrafine particles. Some communities will experience intense exposures and these exposures will be to multiple contaminants simultaneously. Researchers do not know the combined effects of the possible mix of chemicals, but it is an important feature of the UNGD process (Unconventional Natural Gas Development). Health care professionals can use the Report, and specifically Chapter 3, to identify the actual health conditions produced by the reported chemicals.

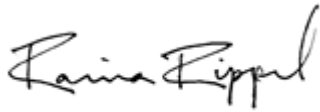

By volume, the largest emissions are NO<sub>2</sub>, CO, VOCs, Formaldehyde, and Particulate Matter. Exposure to these chemicals can cause respiratory and cardiovascular diseases, neurological and developmental diseases and cancer. The New York State Bureau of Vital Statistics reports that, as of 2012, the leading causes of death were heart disease and cancer, followed by chronic lower respiratory disease. What we know from our work and that of researchers across the country is that symptoms associated with UNGD exposure and reported by residents include respiratory, cardiovascular and neurological health effects. Thus, exposure to emissions from these compressor stations may contribute to these prevalent diseases.

**What does this data mean for impacted residents and communities?**

A question often asked of us by residents living near UNGD sites is “how will these emissions affect my health or my community?” This report shows that every compressor station routinely releases large volumes of chemicals associated a variety of diseases and disorders. The level of risk to any individual or community from a compressor station can be estimated by applying specific statistical analyses. The analysis should include modeling the reported chemical emissions from the compressor station based on local weather patterns. The exposure levels at varying distances from the site, and the duration of extreme exposures can then be estimated. The largest emissions by volume are likely to produce the greatest exposures and consequent health impacts.

EHP expects that this compilation of readily available information will be helpful in assuring the health of residents near compressor stations. We welcome feedback, questions and comments on the use of this report.

In good health,

# Purpose of the Report

## Is it Safe?

People living in communities where natural gas compressor stations are sited or are proposed, have repeatedly asked: “Is it safe?” This study represents an attempt to answer that crucial question.

### Industry’s answer

Each of the compressor stations operating in New York State (NYS) have been approved by the state’s Department of Environmental Conservation (DEC) based on the conclusion that they comply with all federal and state air quality requirements.

When members of the public or local officials question the potential health effects of compressor station pollution, invariably the response from industry, EPA, DEC and DOH is that “all legal requirements have been met” -- the clear **implication** being that if these “legal requirements” have been met, there is no reason to be concerned about adverse health effects.

For example, in a public statement issued by Dominion Transmission concerning its New Market Project, it states: “The FERC approved New Market on April 28, 2016 after 23 months of evaluating all environmental, health and safety concerns associated with the project.” Dominion poses the question, “What will be the environmental and public health concerns?” And answers:

Any emissions from the compressor station will comply with all air quality requirements, which are established to protect the public health, safety and welfare. We would not operate the compressor station if we could not operate it according to stringent air quality regulations.

Ensuring compliance with environmental requirements falls either to the Environmental Protection Agency (EPA) or state environmental agencies (states by delegation), depending on the specific permit and rule. (Dominion 2016)

At best, such fact free statements are ill-informed.

In this connection, the three most essential points are these:

First, federal and state environmental laws and regulations are at best designed to protect the general health of regional populations and often fail to protect any single group of locally exposed persons. The “stringent air quality regulations” that Dominion refers to are those established by EPA for the purpose of controlling regional levels of pollution.

Second, “controlling regional levels of air pollution” is not equivalent to ensuring that the air in a region is free of pollutants that cause illness and early death. The air quality in any given region of the state may fully meet all federal and state air standards even though it is saturated with hundreds of dangerous chemicals and tens of thousands of pounds more are added each and every day.

Third, industry’s assurances are hollow. They provide neither the empirical information nor the theoretical framework necessary for the public and local and state officials need to begin to understand the potential adverse health effects of existing and proposed compressor stations.

## Our answer

Our answer to the question, “Is it safe?” is fundamentally different from that of industry and federal and state government.

***In our opinion, the routine emissions surrounding the operation of natural gas compressor stations in New York State (NYS) increase the risk for most major categories of human disease in the state but especially in the communities where they are sited.***

This conclusion is based on (1) an empirical assessment of the volume and content of contaminants released by 18 compressor stations operating under Title V of Clean Air Act in NYS (2) a comprehensive review of peer-reviewed scholarship associating the chemical constituents of those emissions with known and suspected human diseases.

## What this study shows

The air in NY contains chemicals that are linked to 19 of 20 major categories of human disease.

There are 56 operational natural gas compressor stations in New York. Based on data collected by the natural gas industry and reported by EPA, we show that in **a 7-year period 18 of these sites released an estimated 40.2 million toxic pollutants made up of 70 different chemicals**. These 70 chemicals are also linked to 19 of 20 major categories of human disease.

Adding 40.2 million pounds of 70 contaminants to air already contaminated makes the air we breathe **more contaminated** and, by extension, increases the potential for human disease. It is, we think, as simple as that.

A few specific examples:

**Cancer and air pollution:** The International Agency for Research on Cancer, a division of the World Health Organization, is the most authoritative source of information on the effects of chemical and radiologic contamination on human health. In 2016, the Agency released what is perhaps its most important finding: “Outdoor air pollution is carcinogenic to humans.” After reviewing the extensive peer-reviewed literature IARC concluded that (1) in industrialized countries simply breathing the air increases the risk of cancer compared to breathing the uncontaminated air or relatively uncontaminated air and (2) the responsible pollutants are largely the result of human activity, that occur in both rural and urban areas from many different sources.

Although there are hundreds of sources of outdoor air pollution, the source categories that are the largest contributors to most air pollutants in many locations are: vehicle emissions; stationary power generation; other industrial and agricultural emissions; residential heating and cooking; re-emission from terrestrial and aquatic surfaces; the manufacturing, distribution, and use of chemicals; and natural processes. (IARC 2016)

Cancer is the second leading cause of death in the United States and the second leading cause of death in NYS, and in the near future it is very likely to surpass cardiovascular disease, currently the leading cause of death. The 40.2 million pounds of chemicals released by the state’s compressor stations from 2008 to 2014 includes 9.5 million pounds associated with cancer. Of this amount, 7.9 million pounds (83%) is made up of 20 chemicals classified as “known human carcinogens” by one or more authoritative governmental authorities. These cancers are known to cause cancers of the digestive tract (biliary tract, hepatocellular and liver), respiratory tract (lung, nasal cavity and paranasal sinuses), male genital organs (prostate), urinary tract (bladder and kidney), and hemolymphatic organs (acute myeloid leukemia/acute non-lymphocytic leukemia). Adding 5.7 million pounds of carcinogens to the state’s air each year can only increase the risk of cancer.

**Birth defects:** Fifty-seven of the 70 chemicals releases are associated with congenital malformation and deformations, including nervous system, deformations: eye, ear, face and neck, and circulatory system malformations and deformations.

**Reproductive disorders:** Thirty-seven chemicals are associated with diseases of the pelvis, genitals and breasts that affect reproduction. For males, this includes: epididymis, low hormone levels, male impotence, reduced fertility, semen (chemical contamination of semen, low amount of semen and low number of swimming semen), seminal vesicle injury, sperm (abnormalities, irregular shape and low number), and sterility. In women these chemicals are associated with diseases of female pelvic organs as well as noninflammatory disorders of female genital tract--both primary infertility (infertility without any previous pregnancy) and secondary infertility (fertility problems occurring in a couple that has conceived on their own and had a child in the past), as well as cervical erosion, effects on the ovaries (damage, weight changes and unspecified effects), menstrual problems including dysmenorrhea, endometrial stromal polyps, and vagina effects.

**Circulatory system disease:** Cardiovascular disease is the leading cause of death in the United States. In a 7-year period New York's compressor stations released 16 million pounds of cardiovascular toxicants. Compressor station pollutants are linked to hypertensive disease, chronic rheumatic heart diseases, cardiac arrhythmia, heart weight change, increased cardiovascular mortality, acute pulmonary edema, diseases of arteries, arterioles and capillaries (blood vessel changes and regional, general arteriolar or venous dilation).

This information has not previously been reported.

Without hesitation, we can say not only that the volume and known health effects of these pollutants increase the **risk of disease**, but that they will result **in actual illness**. However, given the limited scope of this study, we cannot quantify the nature or extent of potential increased risk.

### The public's right-to-know

In our opinion, the public has a right-to-know the basic facts surrounding the operation of a compressor station, including the number and volume of pollutants and their known or suspected health effects. But beyond this basic information, the public also has the right to expect the opportunity to review a scientifically sound study of the potential health impacts of a compressor station **before** it is built.

### In the State of New York

Neither industry nor government has provided the public with basic data about the extent of compressor station pollution or its likely health effects. In communities where new compressor stations have been planned, the public has asked the industry and state agencies to provide them with "health impact statements," "risk assessments" or "cost-benefit analysis." To public these terms are essentially synonymous, but they represent very different types of studies to the public health community.

In this connection, we would make three points. First and foremost, "health impact statements," "risk assessments" or "cost-benefit analysis" as conducted by federal and state agencies or industry and its paid consultants (a) rarely predict the likely qualitative impact of pollution, as any number of investigators have noted, (b) seldom present relevant information to the public in coherent fashion, or (c) never present a morally persuasive argument why some populations should be subjected against their will to greater levels of pollution with its attendant risk than other (usually more affluent) populations. Generally, the definition of "acceptable risk" adopted by industry and government is one death per 1 million people who are exposed, though various industries have

sought (in some cases successfully) to lower the accepted standard to one death per 100,000 exposed—a tenfold increase.

Second, notwithstanding our skepticism of the value or “health impact statements” and “risk assessments” broadly defined, it is worth noting that we could not find a single existing or proposed compressor station in NYS that has been the subject of such reviews by industry, NYS’s DEC or Department of Health (DOH). Such analyses by the natural gas industry are not those of disinterested investigators. Much the same could be said of FERC, which is widely viewed as a “captive agency,” i.e., an agency effectively controlled by the industry it is responsible for regulating. It is not the responsibility of DEC to perform health-based analyses, nor does EPA routinely require health impact statements. This only leaves the DOH which, unfortunately, is missing in action.

And finally, the lack of information about the potential adverse health effects of compressor stations on local communities has played no role in preventing their construction or expansion.

### **This study’s rationale**

All industrial development involves tradeoffs between short- and long-term economic benefits (real and perceived) and potential harm to human health and the environment.

To date, the criticisms of the expansion of the natural gas industry in the U.S. have focused primarily on four concerns.

**Natural gas versus coal:** First: exaggerated claims for the advantages of using natural gas compared to coal in terms of global warming. As a rule, burning natural gas to produce electricity produces half as much carbon monoxide as coal. While natural gas combustion produces fewer greenhouse gases than coal at the point of combustion, when the chemicals released in the production, transportation and distribution of natural gas are taken into account, the comparative advantage of natural gas are far less clear cut (Dove 2016, Grossman 2015, Moskowitz 2015, UCS, Zielinski S. 2014). Fugitive emissions of methane, roughly 30 times more potent as a heat-trapping gas than carbon dioxide, are of particular concern.

**Climate change:** Second: the more profound and most important argument that whatever natural gas’s relative advantage compared to coal, the planet cannot sustain continued reliance on fossil fuels. In this connection, perhaps most startling is a recent study showing that climate sensitivity is nonlinear. Based on past, current and probable future greenhouse gas emissions, the Earth could heat up as much as 6°C (almost 11°F) in a single lifetime. (Friedrich 2016). Scientists estimate the range of sea rise from 1 to 6 meters (1.3 to 20 feet). The Australian Earth and paleoclimate scientist, Andrew Glikson, describes the likely future: “The consequences of open ended rise in atmospheric CO<sub>2</sub> are manifest in the geological record. . . At 460 ppm CO<sub>2</sub>-equivalent, the climate is tracking close to the upper stability limit of the Antarctic ice sheet, defined at approximately 500 ppm. Once transcended, mitigation measures would hardly be able to re-form the cryosphere. According to Joachim Schellnhuber, Director of the Potsdam Climate Impacts Institute and advisor to the German government: ‘We’re simply talking about the very life support system of this planet.’. . . Humans cannot argue with the physics and chemistry of the atmosphere. What is needed are urgent measures including: Deep cuts in carbon emissions; Parallel Fast track transformation to non-polluting energy utilities – solar, solar-thermal, wind, tide, geothermal, hot rocks; Global reforestation and re-vegetation campaigns, including application of biochar. The alternative does not bear contemplation.” (Glikson 2010) Twenty-two scientists writing in *Nature* depict the situation with equal starkness: “[T]he next few decades offer a brief window of opportunity to minimize [but not prevent] large-scale and potentially catastrophic climate change that will extend longer than the entire history of human civilization thus far. “ (Clark et al. 2016).

In a recent paper reviewing 40 years of climate data and conclusions drawn from that data, researchers found that scientists have underestimated the likelihood of dangerous to catastrophic climate changes.

The historic Paris Agreement calls for limiting global temperature rise to “well below 2 °C.” Because of uncertainties in emission scenarios, climate, and carbon cycle feedback, we interpret the Paris Agreement in terms of three climate risk categories and bring in considerations of low-probability (5%) high-impact (LPHI) warming in addition to the central (~50% probability) value. The current risk category of dangerous warming is extended to more categories, which are defined by us here as follows: >1.5 °C as dangerous; >3 °C as catastrophic; and >5 °C as unknown, implying beyond catastrophic, including existential threats. With unchecked emissions, the central warming can reach the dangerous level within three decades, with the LPHI warming becoming catastrophic by 2050. (Xu and Ramanathan 2017)

**Damage to local environments:** Third: the damage fracking does to local environments in the form of air, water and soil contamination. In February 2014, there were an estimated 1.1 million active oil and gas wells in the U.S. In August 2015, the number of active and dry holes was estimated to be 1.7 million (Kelso 2015). To frack a single well requires up to 5 million gallons of water, and wells can be fracked multiple times—18 times or more. If we assume that each of the 1.1 million active wells were fracked once and used 5 million gallons of water, it means ~12 trillion gallons of water has been contaminated with hundreds of toxic chemicals. This waste water is either collected in surface ponds (many of which are unlined) where it inevitably contaminates surface and groundwater and the air when it vaporizes, or else it is injected underground where it contaminates groundwater and the environment for decades if not centuries.

**Health impacts of fracking:** Fourth: the health impacts of fracking on local communities. A study by the Wall Street Journal examining fracking operations in 11 of the biggest energy producing states found that, “At least 15.3 million Americans live within a mile of a well that has been drilled since 2000. That is more people than live in Michigan or New York City.” (WSJ)

**Health impacts of transportation of natural gas:** To these concerns, we would add a fifth: the health and environmental damage caused by the transportation of natural gas. To our knowledge, this subject has not been previously addressed.

Much of the environmental damage caused by the natural gas industry is largely unseen. The physical damage to local environments where fracking occurs is in part obvious to anyone who cares to look. Roads are cut through forests and hillsides, large bodies of wastewater are collected in ponds and lagoons, dust from diesel trucks and construction equipment is constant as is the noise they make in what were once relatively quiet rural places. But the chemical pollution associated with the extraction, refinement, transportation, storage and combustion of natural gas for energy and heat is largely invisible. Industry advertisements tout natural gas as the “clean alternative” to coal--and in some ways, it is, though it's comparative advantages are wildly exaggerated. But part of what makes natural gas “clean” is that the public can't see the pollution it causes. One reason most people are unaware and unconcerned by pollution associated with unconventional gas development (UGD) is because most don't live in areas where fracking takes place or compressor stations are sited. But more fundamentally we're unconcerned by the UGD pollution because for the most part it's invisible as are its impacts on the public's health--realities which are denied both by the industry and its supporters in and out of government.

The task we set for ourselves here, is to show what the eye can't see: the volume of pollution associated with the transportation of natural gas in New York and its potential to harm human health. The potential health impacts of the large volumes of pollutants generated by natural gas compressor

stations have not been addressed, let alone answered, by those arguing for their construction and expansion.

This report has been prepared to provide the data necessary to understand and evaluate the potential immediate and long-term health outcomes connected with the pollution generated by the routine operations of natural gas compressor stations in New York State (NYS) by examining the actual volume of airborne releases generated by 18 plants and the diseases associated with the chemical pollutants they contain. It is directed at 4 primary audiences:

- Communities with existing compressor stations (to help them recognize the potential adverse health outcomes associated with their continued operation).
- Communities where compressor stations are proposed (to help them understand the potential health threats their construction and operation will introduce).
- Physicians and health practitioners in affected communities.
- Public officials responsible for protecting the safety and health of the public.

There are, by our preliminary estimates, more than 2,000 compressor stations operating under Title V permits in the U.S. (and an equal or greater number of non-Title V stations). Given the volume and toxicity of chemicals released by the 18 Title V facilities we studied, natural gas compressor stations represent a significant national public health problem.

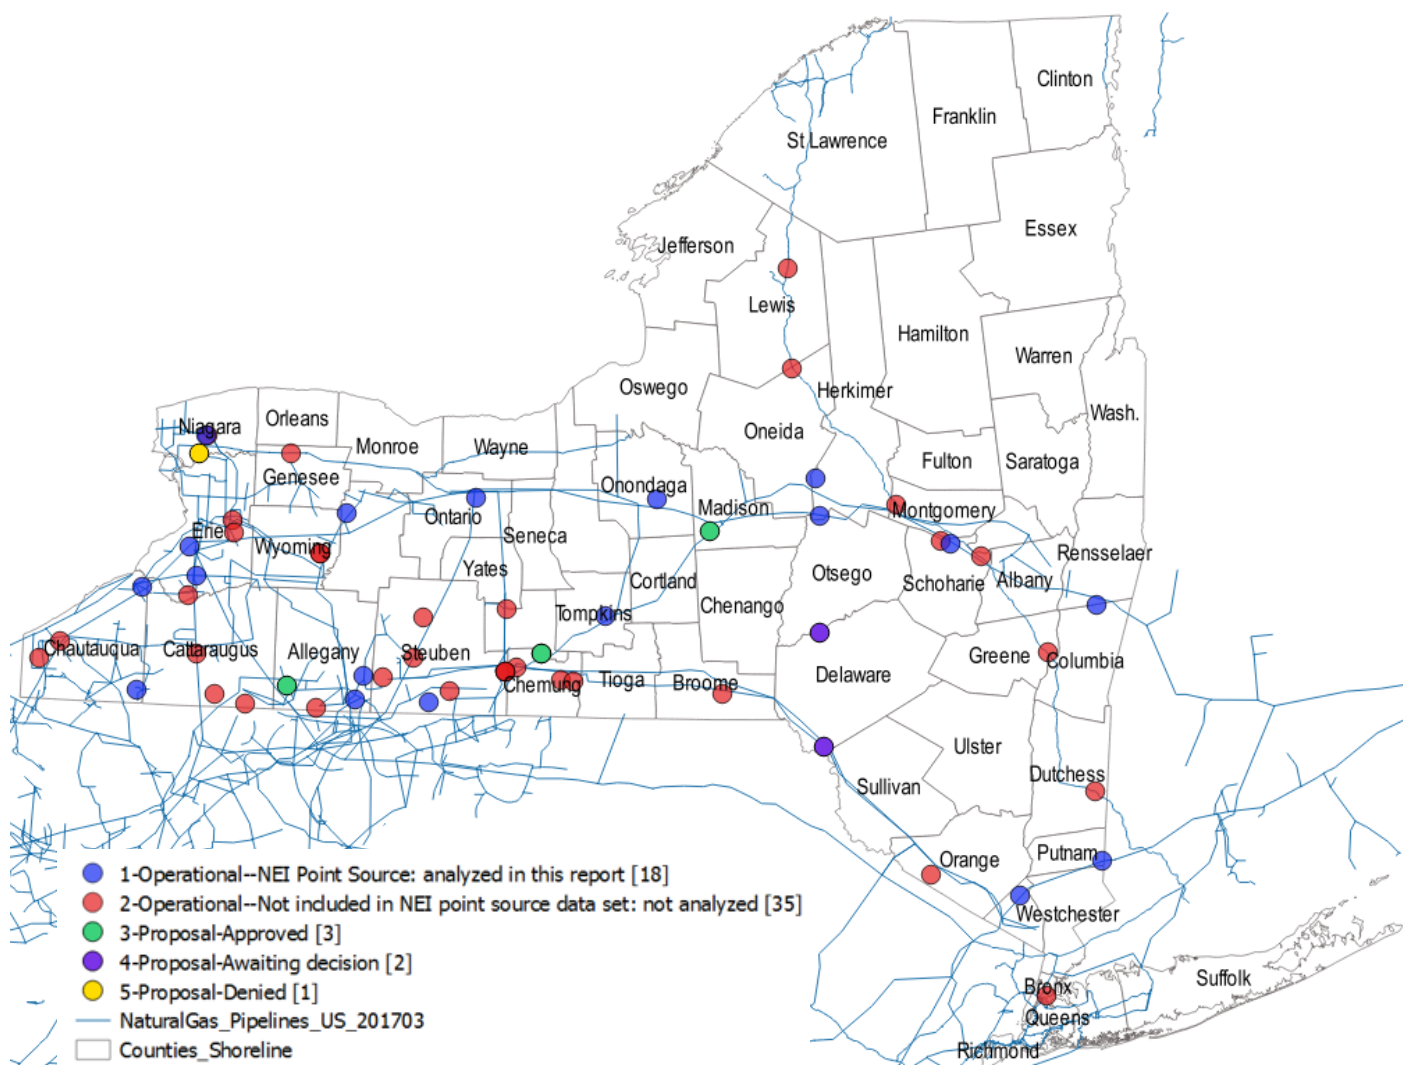

# Executive Summary

## 1. Natural Gas Compressor Stations in NYS

This report analyzes the emissions data for 18 as reported to the National Emissions Inventory (NEI) of the U.S. Environmental Protection Agency (EPA) as point sources of air pollution for the period 2008 to 2014. For the period 2008 to 2014, a total of 58 compressor stations were operational or seeking state and federal approval: operational (54), approved (3), awaiting approval (2) permit denied (1). National Emissions Inventory data is available for 18 of the state's 54-operational natural gas compressor stations. Four operational stations are seeking significant modifications requiring DEC approval. Eighteen of the state's 54 operational compressor stations are classified as "major polluters" and operate under Title V of the Clean Air Act (CAA). Pollution data for these sites is part of NEI's point source data set. These 18 sites are the subject of this analysis. The remaining 37 operational stations are permitted as a NYS "Air State Facility."

GHS emissions data is only available for 8 of the 18 compressor stations for which NEI data is available.

## 2. Total Releases: 40.2 million pounds

For the period 2008 to 2014, an estimated 1.5 billion pounds of point sources of air pollution were reported to NEI by facilities in NYS.

**Releases from the state's national gas compressor stations accounted for approximately 40.2 million pounds or 2.7% of total on-site pollution reported to NEI.**

**This amounts to an annual average of 5.7 million pounds or 478,485 pounds per month, 15,731 pounds per day, 655 pounds per hour.**

**If each of the state's 19.8 million residents were given their fair share, each would receive a little more than 2 pounds over 7 years.**

**Analyzing emissions by each site's 5-digit NAICS code, based on NEI data national gas compressor stations were the 6<sup>th</sup> largest point (stationary) source of air-pollution in NYS.** (If we were to include other sources of air pollution associated with natural gas not included in NAICS 48621, the volume and percentage would be significantly higher. By far the point source of air pollution in NYS is electric power generation (NAICS code 22111) which accounts for approximately 42.3% of the state total. A significant part of this amount is generated by burning natural gas.)

### 3. Total Releases by Chemical: 70

NYS's compressor stations reported releasing 70 individual chemicals or chemicals categories in the period 2008 to 2011 totaling approximately 40 million pounds. The volume of releases varies tremendously. Twelve chemicals have reported releases of less than one pound.

**The largest pollutant, nitrogen oxides, had releases totaling 18.1 million pounds or 45.2% of the aggregate.** Carbon monoxide ranked second (12.4 million pounds or 31%), followed by volatile organic compounds as a group (4.9 million pounds or 12.3%), formaldehyde (1,309,336 pounds or 3.27%), and PM10 Primary (Filt + Cond) (1,259,744 pounds or 3.15%). These five chemicals accounted for 95% of the total.

### 4. Total Releases by Compressor Stations: 18

All 18 compressor stations reporting to NEI reported toxic emissions which totaled 40,192,733 pounds.

The volume of total pollution by station varied widely. The lowest amount reported was one-quarter of a million pounds--a still considerable sum.

**The largest release was from Tennessee Gas Pipeline Company's (TGPC) Compressor Station 245 in Herkimer County: 10.5 million pounds or slightly more than one-quarter (26.1%) of the state total.** TGPC's Compressor Station 229 & TEG Dehydration Facility in Erie County ranked second (5.1 million pounds or 12.8%), followed by TGPC's Compressor Station 249 in Schoharie County (4.3 million pounds or 10.8%).

These three facilities accounted for 19.9 million pounds or slightly less than one-half (49.54%) of all releases.

The top 5 stations accounted for 25.3 million pounds or slightly less (63.1%) than two-thirds of the state total.

#### Total Compressor Station Estimated Releases by Station: 2008-2014

Rank	Facility	County	Pounds	①	②	③	④	⑤	⑥	⑦	⑧	⑨	⑩	⑪
1	TGPC CS 245	Herkimer	10,465,389	①	②	③	④	⑤	⑥	⑦	⑧	⑨	⑩	⑪

40,192,733

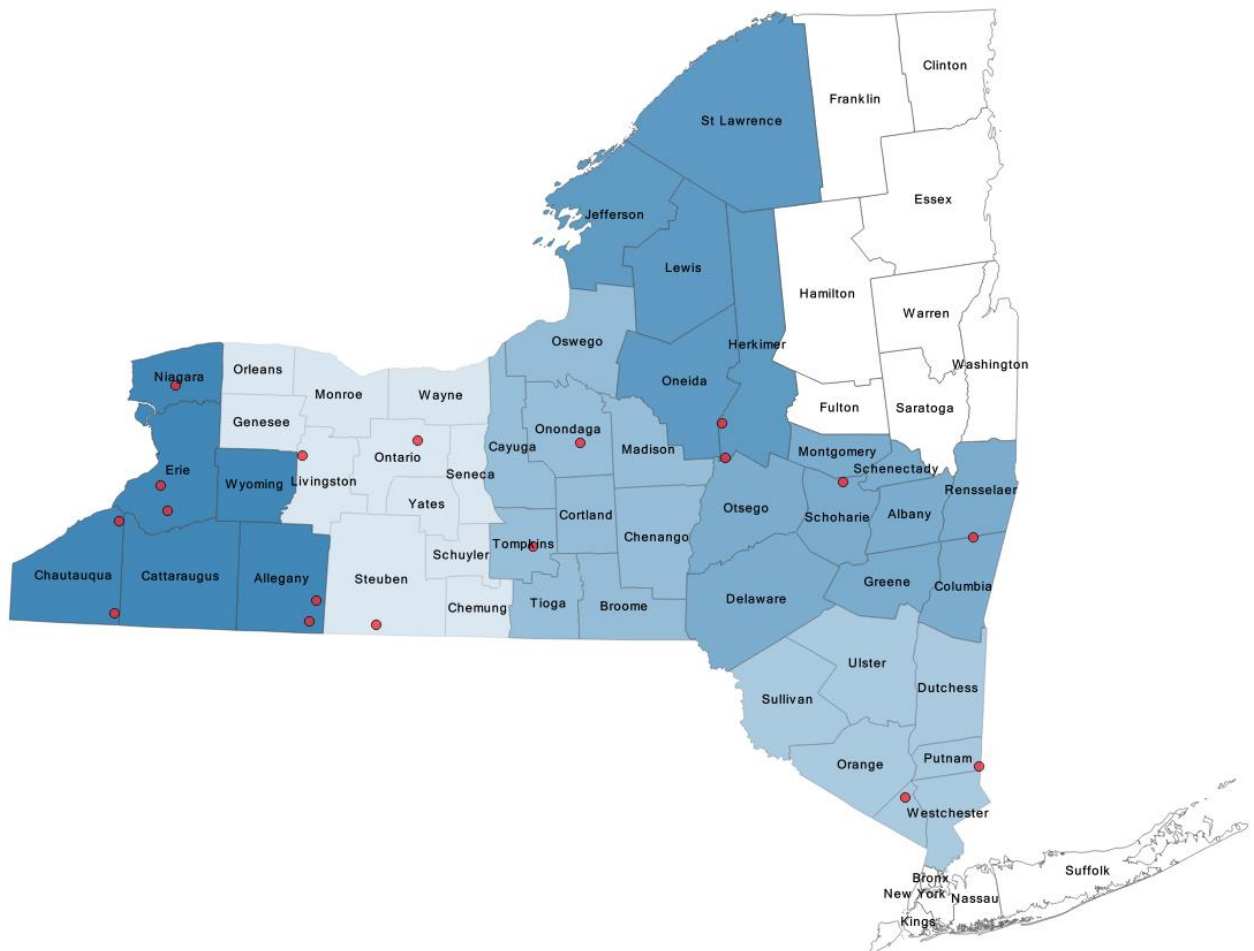

## 5. Total Releases by DEC Regions: 6

NYS DEC divides the state's 62 counties into 9 regions. The 18 operational compressor stations reporting to NEI are in 6 of NYS's 9 DEC regions encompassing 46 counties: 3-Lower Hudson Valley: 2, 4-Capital Region/Northern Catskills: 2, 6-Western Adirondacks/Eastern, Lake Ontario: 2, 7-Central New York: 2, 8-Western Finger Lakes: 3, 9-Western New York: 7.

**Region 9, Western New York, ranked first with an estimated 11.7 million pounds (29.5%), closely followed by Region 2 (10.8 million pounds or 26.7%).** Region 4 reported 6.7 million pounds (16.7%). These three regions accounted for nearly three-fourths (73%) of the state total.

### Total Compressor Station Releases by DEC Region: 2008-2014

Rank	DEC Region	Pounds											
1	9: Western New York	11,646,722	①	②	③	④	⑤	⑥	⑦	⑧	⑨	⑩	⑪
2	6: W. Adirondacks / E. Lake Ontario	10,746,758	①	②	③	④	⑤	⑥	⑦	⑧	⑨	⑩	⑪
3	4: Capital Region / N. Catskills	6,716,946	①	②	③	④	⑤	⑥	⑦				
4	7: Central New York	3,819,820	①	②	③								
5	3: Lower Hudson Valley	3,702,293	①	②	③								
6	8: Western Finger Lakes	3,352,596	①	②	③								

## 6. Total Releases by County: 14

The 18 natural gas compressor stations reporting to NEI are in 14 of NY's 62 counties: Allegany, Chautauqua, Columbia, Erie, Herkimer, Livingston, Niagara, Onondaga, Ontario, Putnam, Rockland, Schoharie, Steuben, and Tompkins. **Herkimer County ranked first with 10.7 million pounds or slightly more than one-fifth of the total (26.7%),** followed by Erie County with 6.9 million pounds (17.1%), and Schoharie with 4.3 million pounds (10.8%). These three counties accounted for slightly more than one-half (54.6%) of all releases: 22 million pounds. The top five counties were responsible for 27.7 million pounds or slightly more than two-thirds (69%) of the aggregate.

### Total Compressor Station Releases by County: 2008-2014

Rank	County	DEC Region	Pounds	1	2	3	4	5	6	7	8	9	10	7
1	Herkimer	6: W Adirondacks/E. L Ontario	10,746,757	1	2	3	4	5	6	7	8	9	10	7
2	Erie	9: Western New York	6,857,598	1	2	3	4	5	6	9				
3	Schoharie	4: Capital Region/N. Catskills	4,323,285	1	2	3	4	3						
4	Onondaga	7: Central New York	3,039,661	1	2	3								
5	Allegany	9: Western New York	2,741,523	1	2	7								
6	Columbia	4: Capital Region/N. Catskills	2,393,660	1	2	4								
7	Ontario	8: Western Finger Lakes	2,298,394	1	2	3								
8	Rockland	3: Lower Hudson Valley	2,013,478	1	2									
9	Putnam	3: Lower Hudson Valley	1,688,814	1	7									
10	Chautauqua	9: Western New York	1,561,991	1	6									
11	Steuben	8: Western Finger Lakes	829,223	8										
12	Tompkins	7: Central New York	780,159	8										
13	Niagara	9: Western New York	485,609	5										
14	Livingston	8: Western Finger Lakes	224,978	2										

## 7. Total Releases by Zip Codes: 18

The 18 operational compressor stations reporting to NEI are in 18 zip codes. **Compressor stations were responsible for 92% of all recorded industrial emissions in their respective zip codes.** In 14 of these zip codes, emissions from natural gas compressor stations were the **only** point source of air pollution reported by NEI.

## 8. Total Releases per Square Mile

The distance and direction pollution travels from each natural gas compressor station on any given day (or any hour) is dependent on many factors, including: the height of the stack, chemical composition of the fuel, chemical composition of emissions, meteorological conditions (wind speed and direction, atmospheric stability and cloud cover), as well as local and regional geographical features.

Absent an independent analysis, most epidemiological studies assume that if stacks are short (which is the case for NYS compressor stations), on a typical day most air pollution that is inhaled has traveled a relatively short distance from a plant—something on the order of less than 10 miles—recognizing that on certain days pollution from a single plant can travel hundreds or even thousands of miles before it reaches the ground and is inhaled.

If we assume that the 10.5 million pounds of toxic releases generated by the largest polluter, TGPC's Compressor Station 245, fell within a 1-mile radius of the plant (a 2-mile diameter circle of 3.14 square miles), it amounts to 3.3 million pounds per square mile or approximately 0.12 pounds per square foot.

If, instead, we assume it fell within 1.5-mile radius of the plant (a 3-mile diameter circle of 7.07 square miles), it amounts to 1.5 million pounds per square mile.

## 9. Total Releases: Circular Area Population Profiles

The number of people in New York State exposed to air pollution from natural gas compressor stations is significantly larger than generally recognized.

### 10-Mile Radius

Air pollution from a compressor station can easily travel 10 miles or more before returning to ground level.

***Approximately 1.6 million people live within 10 miles of the 18 natural gas compressor stations analyzed in this report—more than 1 out of 8 New Yorkers or 12.5% of the population, which works out to about 25 pounds per person over 7 years.***

At this 10-mile radius, people in ~31 counties are potentially breathing air contaminated by compressor station pollutants: NY (27), CT (1), and PA (3).

## 20-Mile Radius

Expanded to 20 miles the number potentially affected is 5.7 million (more than 1 out of every 3 people) in 52 counties: NY (39), CT (3), MA (1), NJ (3), and PA (6).

## 2-Mile Radius

Approximately 33,516 people live within a 2-mile radius. If we assume all the pollution was limited to this radius, it works out to 1,201 pounds per person over 7 years.

(See section 2.5c.1. for more details)

## 10. Total Releases by Health Effects

The 70 chemicals released by NYS's natural gas compressor stations are linked to all 17 of the major categories of human disease as classified by the International Statistical Classification of Diseases and Related Health Problems, 10<sup>th</sup> edition (ICD-10). These are summarized in the table below.

Most chemicals are known to cause multiple categories of diseases. Formaldehyde is a good example. NEI shows releases totaling approximately 1.3 million pounds of this chemical.

Formaldehyde is a known human carcinogen, so it is included as a chemical associated with neoplasms (ICD-10, Chapter 2). But it is also associated with virtually every other major category of human disease, so it would be included as contributing to the totals in the table below for chapters 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14, 15, 16, 17, and 18.

**There were, for example 9.5 million pounds of 59 chemicals related to neoplastic diseases (malignant and benign neoplasms) released by 18 facilities in 14 counties, averaging 1.4 million pounds annually (ICD-10, Ch. 2).** Or, to put it differently, 23.9% of all 40.2 million pounds of toxic chemicals released are carcinogens.

There were 16.2 million pounds of pollutants associated with circulatory diseases such as heart attacks and strokes (ICD-10, Ch. 9). The table below lists health effects by their ICD Chapter.

### Toxic Releases by ICD-10 Chapter

New York State Natural Gas Compressor Stations: 2008 to 2014

ICD Ch.	Disease \ Disorders	Chemicals	Facilities	Counties	DEC Reg.	Pounds Annual Average	Pounds Total	% of Total Lbs.
1	Certain infectious and parasitic diseases	1	18	14	9	2,583,224	18,082,570	45.0
2	Neoplasms (malignant and benign)	59	18	14	9	1,362,610	9,538,272	23.9

## NYS Compressor Station Toxicants: 2008-2014

<b>Total Releases by ICD-10 Disease Category (millions of pounds)</b>	<b>~40.2</b>
1. Certain infectious and parasitic diseases*	18.1
2. Neoplasms (malignant and benign)	9.5
3. Blood and blood form, certain immune disorders	18.8
4. Endocrine and metabolic	18.8
5. Mental and behavioral	18.7
6. Nervous system	19.0
7. Eye and adnexa	24.8
8. Ear and mastoid process	17.5
9. Circulatory system	16.3
10. Respiratory system	39.6
11. Digestive system	38.5
12. Skin and subcutaneous tissue	27.7
13. Musculoskeletal system\connective tissue	1.2
14. Genitourinary system	39.9
Urinary system	6.4
Reproductive system: Pelvis, genitals and breasts	40.0
15. Pregnancy, childbirth, puerperium	19.6
16. Certain conditions originating in the perinatal period	22.5
17. Birth defects, chromosomal abnormalities	39.6
18. Symptoms, signs, findings nec	39.6

\* Systemic effects resulting from the release of greenhouse gases.

## 11. Visualizing the Data

### Scenario 1

It's difficult to visualize what 40.2 million pounds of pollution looks like.

The following might help.

Everyone's familiar with a 5-pound bag of flour. There's one in every kitchen.

Assume that the 40.2 million pounds of toxic pollution generated by the state's 18 compressor stations has the same density as flour, i.e., that 5-pounds of pollution would fit in a bag equivalent in size to a 5-pound bag of flour.

To put the 40.2 million pounds of compressor station pollution in 5-pound bags would require 8,038,545 bags.

### Scenario 2

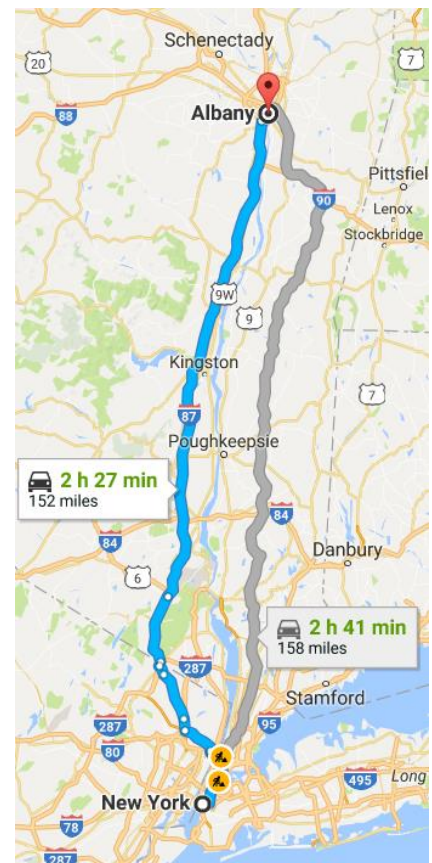

Let's go a step further. Let's say we wanted to take our 8 million bags of toxic pollution for a ride.

Assume we loaded all 7 years of compressor station pollution onto  $\frac{1}{2}$ -ton pickup trucks.

Each pickup could safely carry 1,000 pounds or 200 5-pound bags.

So, we'd have to load up 40,193 1-ton pickups (40.2 million pounds / 1,000)

Let's say each pickup is 20' long and we were backed up on the highway literally bumper to bumper: Our line of 40,193 1-ton pickup trucks would stretch 152 miles-- exactly the distance from New York City to Albany.

### Scenario 3

Another scenario.

Let's assume we aren't stuck in traffic and instead our 40,193 trucks filled with compressor station pollution are traveling 65 mph on the nation's highways with 576 feet between each truck (the distance the average driver needs to react in 6 seconds).

In this case our pollution convey would stretch about 4,537 miles (40,193 trucks x 596 feet / 5,280 feet) -- almost long enough to stretch from the easternmost location in the U.S., Houlton Maine, down to Miami, back up to Tampa, along the Gulf Coast to Houston, across Texas, New Mexico, Arizona and California to Los Angeles.

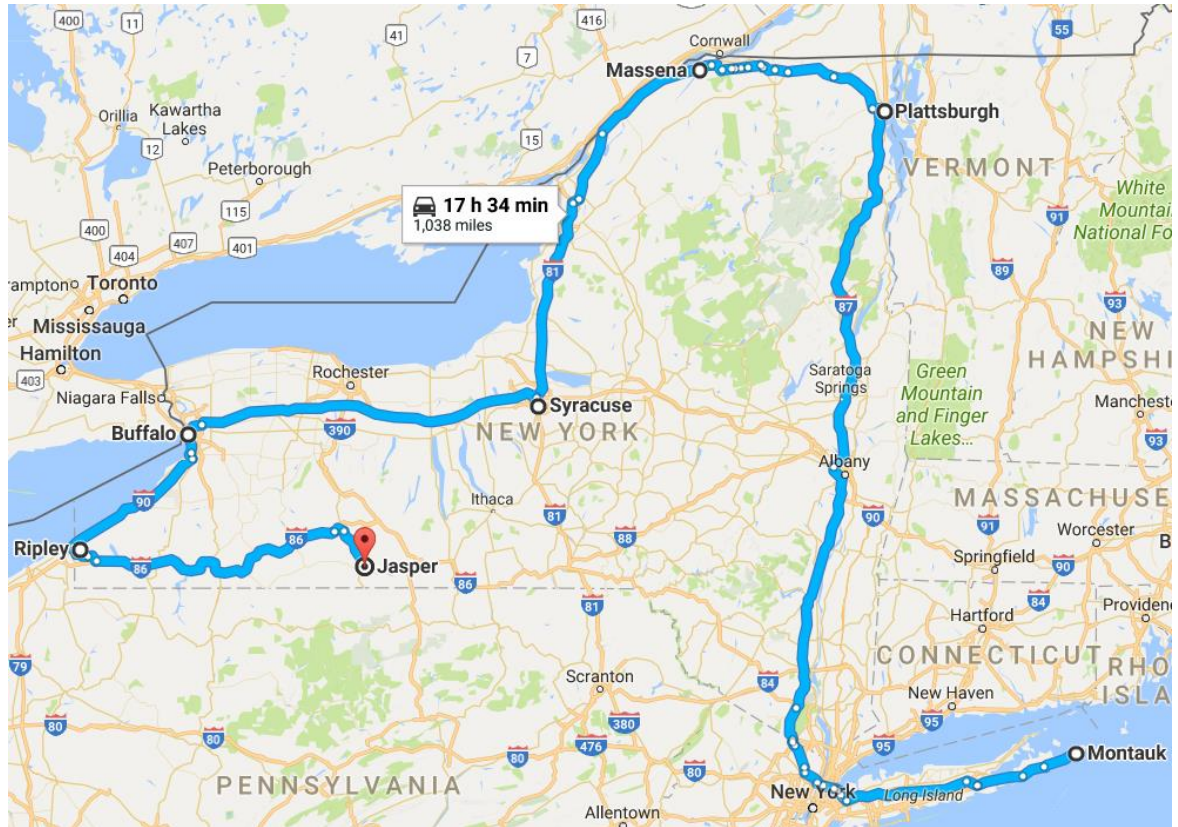

## Scenario 4

A flour bags is 8" tall.

If we laid each of our 8,038,545 bags on their side they would stretch approximately 1,034 miles.

This is enough bags to line the interstates from Montauk Long Island, up to Plattsburgh, west to Massena, down to Syracuse, went to Buffalo, down to Ripley and east to Jasper.

## Scenario 5

Everyone knows what a football field looks like.

New Era Field, home to the Buffalo Bills, is the only professional football field in NYS.

A football field measures 160' x 360' (57,600 sq. ft.).

Our flour bags measure 8" x 6" x 5".

If we lay a flour bag on its widest sides, it measures 8" x 6" or 48 sq. inches.

It takes 14,400 bags to cover a football field with a single layer of 5-lb. bags to a height of 5".

If we placed all 8 million bags one atop the other, we could cover New Era Field to a height of about 97' -- roughly the height of a 10-story office building.

A second scenario: If we laid the bags next to each other along the 5" dimension (the shortest), since a football field is 100 yards or 300 feet,  $0.417 \text{ ft per bag} \times 8.04 \text{ million bags} \times 1 \text{ mile per } 5280 \text{ ft}$  yields 634 miles. Since a football field is 0.057 mi long, we would need  $634/0.057$  or about 11,000 football fields all lined up one after the other to "hold" this line of bags.

## Contents of the Report

This report is divided into four chapters.

- Chapter 1, Background: provides a brief review of the issues which motivated this report.
- Chapter 2, Compressor Station Releases: identifies the locations of natural gas compressor stations in New York State (NYS) and the total volume of air pollution they generate based on the three most recent years of data collected by the U.S. Environmental Protection Agency's (EPA) National Emissions Inventory. Detailed analysis of total air pollution is analyzed by chemical, chemical category, NYS Department of Environmental Conservation (DEC) Regions, counties, and zip codes.
- Chapter 3, Health Effects: provides a detailed analysis of compressor station air pollutants for each of 17 major disease categories as defined by the International Classification of Diseases, 10th edition (ICD-10). For each disease category, gas compressor station air pollutants are analyzed by chemicals, by ICD categorization, facilities, DEC regions, and by counties.
- Chapter 4, Facilities: provides a profile of each of the compressor station studied in this report along with a summary of the health effects associated with the chemicals each generates.

## Materials and Methods

### Health effects

To facilitate the identification of toxic exposures and their potential health and environmental impacts, the author has created several proprietary SQL-compliant databases used in environmental and epidemiological studies:

1. Chemical Database: Contains essential data on slightly more than 21,000 unique chemicals or chemical categories, including names, synonyms, identification numbers, chemical and physical characteristics, and inclusion in federal, state and international reporting programs.
2. Occupational Database: Contains essential data on approximately 500 occupations or occupational grouping for which there are epidemiological assessments. Occupations are categorized according to the U.S. Bureau of Labor Statistics Standard Occupational Classification (2010).
3. Health Effects Database: Indexes approximately 120,000 peer-reviewed studies examining the impacts of toxic chemicals on human health and the environment. Each article is indexed by the relevant ICD-10 code. Fields include: chemical name or identifier, author, full reference, PMID, DOI, subject (human/animal), acute/chronic exposure, route of exposure (inhalation, skin, drinking water, diet, etc.). This database can be used to identify all health effects associated with a specific chemical or chemical category.

## U.S. National Emissions Inventory

The rationale for the creation of NEI and some of its limitations are described in the draft of NEI's Technical Support Document, published in June 2014 (USEPA 2014):

The NEI is created to provide EPA, federal and state decision makers, the U.S. public, and other countries the U.S.'s best and most complete estimates of CAP and HAP emissions. While EPA is not directly obligated to create the NEI under the Clean Air Act, the Act authorizes the EPA Administrator to implement data collection efforts needed to properly administer the NAAQS program. Therefore, the Office of Air Quality Planning and Standards (OAQPS) maintains the NEI program in support of the NAAQS. Furthermore, the Clean Air Act requires states to submit emissions to EPA as part of their State Implementation Plans (SIPs) that describe how they will attain the NAAQS. The NEI is used as a starting point for many SIP inventory development efforts and for states to obtain emissions from other states needed for their modeled attainment demonstrations.

While the NAAQS program is the basis on which EPA collects CAP emissions from the state, local, and tribal (S/L/T) air agencies, it does not require collection of HAP emissions. For this reason, the **HAP reporting requirements are voluntary**. [authors' emphasis] Nevertheless, the HAP emissions are an essential part of the NEI program. These emissions estimates allow EPA to assess progress in meeting HAP reduction goals described in the Clean Air Act 4 amendments of 1990. These reductions seek to reduce the negative impacts to people of HAP emissions in the environment, and the NEI allows EPA to assess how much emissions have been reduced since 1990.

If "HAP reporting requirements are voluntary" by extension it seems reasonable to conclude that EPA isn't legally obligated to analyze the results of the inventory to identify all potential health impacts, to prioritize chemicals in terms of their greatest harm to health, or communicate this information to the general public or state regulators effectively.

The National Emissions Inventory is available to the public on EPA's website.

Data is published every 3 years. This report uses the last 3 years of published data: 2008, 2011, and 2014.

To estimate total releases over the 7-year period from 2008 through 2014, the average for 3 years was determined and multiplied by 7. Given the characteristics of the data, performing these calculations at different levels (e.g., facility versus country) sometimes produces slightly different totals, though the difference is small and not statistically meaningful.

## U.S. EPA Greenhouse Gas Inventory

The major source of emissions of greenhouse gases is EPA's Greenhouse Gas Inventory:

[T]he U.S. Greenhouse Gas Inventories developed by the U.S. government to meet U.S. commitments under the United Nations Framework Convention on Climate Change (UNFCCC). Article 4.1a of the UNFCCC requires that all countries periodically publish and make available to the Conference of the Parties (COP) inventories of anthropogenic emissions and removals by sinks of all greenhouse gases not controlled by the Montreal Protocol.

Subsequent decisions by the COP require the United States to submit these reports on an annual basis and include emissions of carbon dioxide (CO<sub>2</sub>), methane (CH<sub>4</sub>), nitrous oxide (N<sub>2</sub>O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF<sub>6</sub>) and removal of these gases by sinks. (EPA GGI).

## Available EPA Data: Chemicals, Emissions Types, Years

Data on pollution from natural gas compressor stations in New York State is drawn from 2 federal sources: U.S. EPA National Emissions Inventory (point sources) and U.S. EPA Greenhouse Gas Inventory.

### Stationary Sources

NEI's point source data set provides data on releases from stationary sources (aka point or stack) and provides information on 70 specific chemicals.

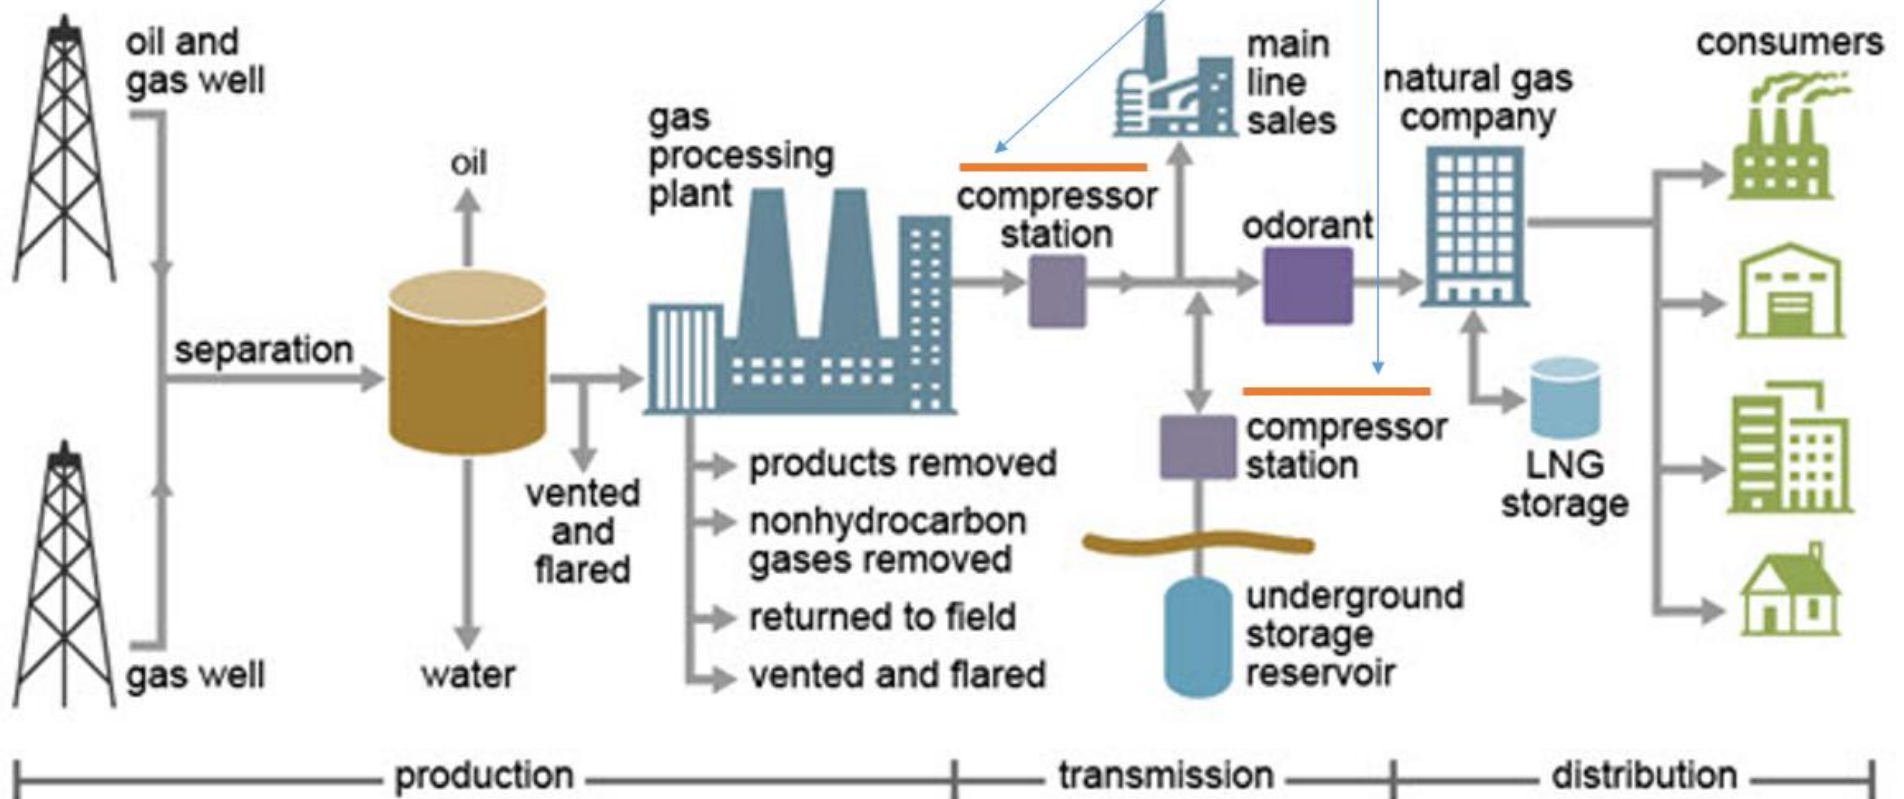

EPA's GHGI provides data on 2 chemicals not included in NEI's point data set for compressor stations: carbon dioxide and methane.

### Fugitive Releases

EPA's GHGI provides data on 3 chemicals from fugitive sources at the compressor station site: carbon dioxide, methane and NO<sub>x</sub>. However, data is only available for 8 of NYS's 18 Title V compressor stations and this only begins in 2010.

## National Fuel's planned compressor station in Hinsdale (Cattaraugus County)

Source: National Fuel Gas Supply Corp.

## Years of available data

EPA NEI reports data every third year—data is available for 2008, 2011 and 2014.

The data reported for NYS is fairly complete: 17 stations report data for all 3 years, while one reports for 2008 and 2011 but not for 2014.

The national data seems fairly incomplete: (a) 409 compressor stations that reported releases in 2008 had not data for 2011, and (b) 196 that reported data in 2008 showed no data for 2014, and (c) 426 that reported data in 2011 showed no data for 2014. In a few cases we suspect this is due to plant modifications but it is unlikely that this explains the extent of missing data.

# Chapter 1. Background

# 1. Introduction

## 1.1. Pollution as a Cause of Human Disease

The causes of human disease are various and complex. The siting of industrial facilities is inherently problematic and political. Communities facing the prospect of a new natural gas compressor station or the expansion of an existing station, must grapple with both sets of concerns and, more difficult still, the specific question of how compressor station emissions may potentially harm human health.

It was only in relatively recent years that a large part of the scientific community accepted the view that environmental and occupational exposures to man-made chemicals and radiation are a significant threat to health. The creation of the U.S. Environmental Protection Agency (EPA) and the U.S. Occupational Agency (OSHA) in 1970 and the passage of the National Cancer Act the next year were each **partly** motivated by growing evidence of pollution as a cause of human diseases.

In the near half-century since these agencies and programs were created, significant progress has been made in reducing pollution in the U.S. But when the actual history is studied, it is clear that these advances only came because of sustained political efforts by people outside of government attempting to pressure those in government to do the right thing over the opposition of vested economic interests. Legislative measures are generally only taken many years after scientific warnings are first raised. And more often than not, these long overdue legislative measures are half-steps that are inadequately funded and ineffectively enforced.

While the positive steps that have been made should be recognized, the difference between what society needed to do to confront the problem of pollution and what has actually been done, is stark.

The two leading causes of death in the U.S. are cardiovascular disease and cancer. Environmental and occupational exposure to chemicals are a significant risk factor for both diseases. Based on data reported by the natural gas industry, this report shows that 18 compressor stations operating in New York State released a total of more than 40 million pounds of toxic air pollution in the period from 2008 to 2014, including 16.3 million pounds association with cardiovascular disease and 9.5 million pounds of carcinogens.

We are approaching the 50<sup>th</sup> anniversary of the creation of EPA and OSHA and President Nixon's declaration of "The War on Cancer". In 50 years the nation has made little progress in protecting the public from environmental exposures to known and suspected human carcinogens. Perhaps most importantly, this includes the failure of the existing approach to identifying and communicating environmental and occupational chemical risk.

## 1.2. President's Cancer Panel (2010)

The long-recognized failure of federal agencies to address the environmental causes of cancer led to the creation of the President's Cancer Panel (PCP) which between September 2008 and January 2009 convened four national meetings "to assess the state of environmental cancer research, policy and programs addressing known and potential effects of environmental exposure on cancer." More specifically, the Panel's assigned task was to appraise the National Cancer Program as established in accordance with the National Cancer Act of 1971 (P.L. 92-218), the Health Research Extension Act of 1987 (P.L. 99-158), the National Institutes of Health Revitalization Act of 1993 (P.L. 103-43), and Title V, Part A, Public Health Service Act (42 U.S.C. 281 et seq.). The Panel's overarching conclusion:

Research on environmental causes of cancer has been limited by low priority and inadequate funding. . . There is a lack of emphasis on environmental research as a route to primary cancer prevention. . . Cancer prevention efforts have focused narrowly on smoking, other lifestyle behaviors and chemo-preventive interventions. Scientific evidence on individual and multiple environmental exposure effects on disease initiation and outcomes, and consequent health system and societal costs, are not being adequately integrated into national policy decisions and strategies for disease prevention, health care access and health system reform. (U.S. DHHS 2010)

With regard to this paper's primary concern, identifying the potential health risk associated with routine operations of natural gas compressor stations, four of the Panels critical conclusions are particularly relevant:

### **1. The Present Approach to Risk Assessment is Inadequate:**

[Exposure assessment] is needed more broadly to evaluate cancer risk associated with workplace or environmental exposures in the aggregate. In the U.S., most available exposure assessments are badly outdated. A comprehensive assessment of the extent of all environmental and workplace exposures, for example, has not been conducted since the flawed Doll and Peto estimates published in 1981 (Doll and Peto 1981). Although OSHA's mission is to ensure that workplace environments are safe, it does not conduct a comprehensive national review of carcinogens in the workplace. (U.S. DHHS 2010, p. 15)

Cancer risk assessment also is hampered by lack of access to existing exposure data, especially for occupational/industrial exposures, and regarding levels of radon, asbestos, and other contaminants in schools and day care centers. (U.S. DHHS 2010, p. viii)

Research Methodology and Data Collection Issues: In addition to measurement and standard-setting issues, environmental and occupational cancer research and assessment have suffered from methodologic and data collection weaknesses. (U.S. DHHS 2010, p. 10)

Testimony, Paul Schulte, NIOSH: Right now, the numbers for how many workers are exposed to most of the known carcinogens are 20 to 30 years old so we don't really know what the contemporary workforce is experiencing in terms of exposure.

Testimony, Sandra Steingraber, Ithaca College: Estimates of "attributable fractions" of the cancer burden due to occupation (approximately 4 percent), pollution (2 percent), industrial products (<1 percent), and medicines and medical procedures

(1 percent) are now believed to underestimate significantly the true toll of cancer related to these exposures.” (U.S. DHHS 2010, p. 2)

Recommendation: A thorough new assessment of workplace chemical and other exposures is needed to quantify current health risks. Previous estimates of occupational cancer risk are outdated and should no longer be used by government or industry. (xii)

Recommendation: Measurement tool development and exposure assessment research, including the development of new research models and endpoints, should be accelerated to enable better quantification of exposures at individual, occupational, and population levels. (U.S. DHHS 2010, p. xiv)

Recommendation: Epidemiologic and hazard assessment research must be continued and strengthened in areas in which the evidence is unclear, especially research on workplace exposures, the impact of in utero and childhood exposures, and exposures that appear to have multigenerational effects. Current funding for federally supported occupational and environmental epidemiologic cancer research is inadequate. (U.S. DHHS 2010, p. 105)

## **2. Workers, Other Populations with Known Exposures, and the General Public Require Full Disclosure of knowledge about Environmental Cancer Risks**

Individuals and communities are not being provided all available information about environmental exposures they have experienced, the cumulative effects of such exposures, and how to minimize harmful exposures. (U.S. DHHS 2010, p. ix)

Continued Epidemiologic and Other Environmental Cancer Research Is Needed: Cancer risk assessment . . . is hampered by lack of access to existing exposure data, especially for occupational/industrial exposures, and regarding levels of radon, asbestos, and other contaminants in schools and day care centers. (U.S. DHHS 2010, p. 98)

## **3. Medical Professionals Need to Consider Occupational and Environmental Factors When Diagnosing Patient Illness**

Physicians and other medical professionals rarely ask patients about their workplace and home environments when taking a medical history. Such information can be invaluable in discovering underlying causes of disease. Moreover, gathering this information would contribute substantially to the body of knowledge on environmental cancer risk. (U.S. DHHS 2010, p. ix)

## **4. Inadequate Funding**

Testimony: Elizabeth Fontham, Louisiana State University: Unfortunately, while budgets have waxed and waned on the federal level, a consistent finding, I would say, is that occupational and environmental exposures have been under addressed. (U.S. DHHS 2010, p. 5)

NIOSH Work Group: In 1996, NIOSH convened a group of experts from academia, business, labor, and government to identify the gaps in occupational cancer research methods.<sup>60</sup> The group’s recommendations for strengthening research methods, which became part of NIOSH’s National Occupational Research Agenda, focused on four broad areas: identification of occupational carcinogens, design of epidemiologic studies, risk assessment, and primary and secondary prevention (U.S. DHHS 2010, p. 10)

For those who believe that environmental factors are a much-neglected risk factor for cancer (as well as for non-neoplastic diseases) PCP's conclusion is an important step in the right direction. (Everything the Panel has stated about the lack of attention to environmental and occupational causes of cancer could, in our opinion, also be said of non-neoplastic diseases.)

It is, we think, remarkable that those advancing the view that environmental exposures play only the smallest role in human cancer do so without ever discussing let alone conducting a detailed assessment of exposure, i.e., the extent to which Americans are exposed to chemical and radiologic carcinogens.

The starting place of scientific inquiry is identifying all possible factors which might in some measure affect the phenomenon under investigation. How is it possible to conclude that environmental causes are bit players without first having examined fundamental questions related to the extent and significance of exposures to man-made carcinogens? Such questions include: the total pounds of chemicals manufactured and imported, their number and characteristics, the number of chemicals approved for commercial use, the number and volume of chemicals produced by combustion (not intentionally manufactured), where and how exposures occur, their persistence in the environment, chemical synergism, issues related to exposure assessment, and the number of carcinogens found in human urine, blood and adipose tissue as well as evidence of neo-natal contamination?

Any summary account attempting to answer the question (however tentatively) "What causes cancer?" must include an analysis of these critical issues as well as a number of pertinent methodological concerns. Absent this framework any analysis which purports to claim that X% of Y cancers are caused by Z (or some combination of factors) is logically unsound—all of the possible relevant explanations have not been considered.

In this paper, we show that 18 of the state's ~40 natural gas compressor stations released an estimated 40.2 million pounds of toxic into the air over a 7-year period—an annual average of about 5.7 million pounds. The 7-year total included an estimated 9.5 million pounds of carcinogens (80% of which are classified as "known human carcinogens")—approximately 1.4 million pounds a year. The significance of this finding we believe, speaks for itself. Would a reasonable person who is presented with fact persist in the assertion that environmental factors are only a small causal factor? We don't think so.

Our establishing the extent of carcinogenic exposures in a single facility does not prove that they cause a specific percentage of a given cancer or all cancers at this work site, but it does demonstrate that an analysis consistent with the principles, methods and logic of scientific inquiry must seriously take environmental considerations into account.

In *Discourse on Method* Descartes advises that "when it is not in our power to determine what is true, we ought to follow what is most probable." It is this precept that has been the hallmark of modern science. It is, however, one which cannot be said to guide the nation's approach to preventing cancer. The tired assertion endlessly repeated that most cancers have little or no connection to environmental pollution is made without context or reference to physical realities--the extent and characteristics of chemical contamination and its documented effects. The environmental hypothesis is in no meaningful way refuted. It is simply dismissed. ***The physical reality of widespread, unavoidable chemical contamination is the large picture that must frame any meaningful discussion of cancer's etiology as well as risk assessment.***

### 1.3. Outdoor Air and Particulate Air Pollution: Known Human Carcinogens

What is that larger picture?

***In 2013, the International Association for Research on Cancer, the specialized cancer agency of the World Health Organization, classified outdoor air as a known human carcinogen and a leading cause of cancer deaths.***

IARC's study was "based on the independent review of more than 1,000 scientific papers from studies on five continents. The reviewed studies analyze the carcinogenicity of various pollutants present in outdoor air pollution, especially particulate matter and transportation-related pollution. The evaluation is driven by findings from large epidemiologic studies that included millions of people living in Europe, North and South America, and Asia."

After reviewing the extensive scientific literature IARC concluded that there is sufficient evidence to conclude that exposure to outdoor air pollution is a cause of lung cancer (Group 1) and that there is a positive association with an increased risk of bladder cancer.

From 2008 to 2014, NYS's natural gas compressor stations released an estimated 2.9 million pounds of particulate pollution, a major component of outdoor air pollution. Particulate airborne pollution was evaluated separately by IARC and was also classified as carcinogenic to humans (Group 1).

The IARC evaluation showed an increasing risk of lung cancer with increasing levels of exposure to particulate matter and air pollution. Although the composition of air pollution and levels of exposure can vary dramatically between locations, the conclusions of the Working Group apply to all regions of the world.

A recent Chinese study observed that cancer is rising in China in significant part to air pollution but that policies to systematically use cancer registry statistics and air pollution data to understand this problem are inadequate (which is also true in this country).

Analyses on the cancer registry data show that cancer burden related to air pollution is on the rise in China and will likely increase further, but there is a lack of data to accurately predict the cancer burden. Past experience from other countries has sounded alarm of the link between air pollution and cancer. The quantitative association requires dedicated research as well as establishment of needed monitoring infrastructures and cancer registries. The air pollution-cancer link is a serious public health issue that needs urgent investigation. (Huang et al. 2014)

#### 1.4. Expansion of Fracking Operations and Natural Gas Compressor Stations in the U.S.

In 2010, the U.S. Department of Energy reported there were 510,000 operational natural gas wells in the U.S., almost twice as many as there were in 2000, and that on average 13,000 new wells drilled each year during this 10-year period.

To keep pace with the unprecedented expansion of fracking operations, over the last two years the number of natural gas pipeline compressor stations has grown significantly. In 1996, there were approximately 1,047 compressor stations attached to the mainline grid with an installed horsepower of 13.4 million, capable of a daily combined throughput of 743 billion cubic feet. Ten years later there were 1,201 comparable stations (an increase of 17%) with 16.9 million installed horsepower capable of 881 billion cubic feet or a 19% increase in output. (EIA 2007-11)

Note: EIA has determined that publication of this figure does not raise security concerns, based on the application of Federal Geographic Data Committee's Guidelines for Providing Appropriate Access to Geospatial Data in Response to Security Concerns.  
Source: Energy Information Administration, Natural Gas Division, Natural Gas Transportation Information System, Compressor Station Database.

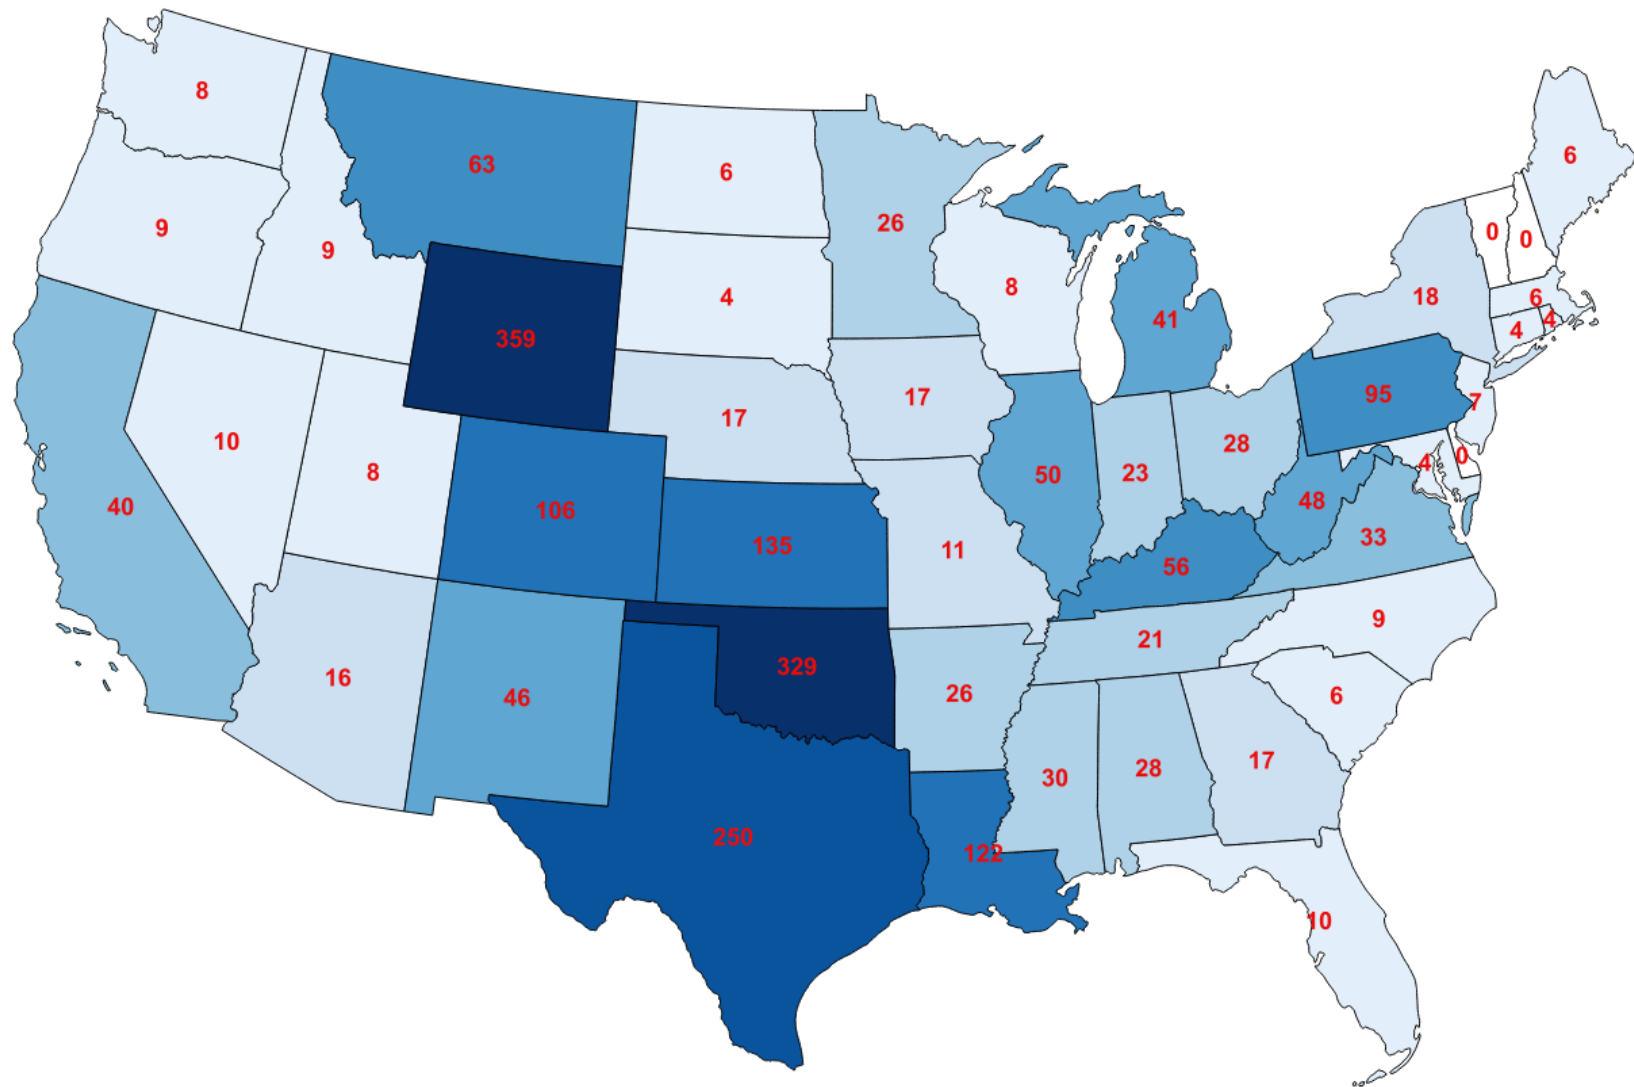

Our own analysis of NEI's data for the period 2008 to 2014 shows 2,177 compressor stations as identified by NAICS 48261.

In NYS Title V compressor stations are classified as 48621. It is unclear to the authors whether all 2,177 stations with NAICS 48621 operate under a Title V permit.

***Our preliminary estimate is that these 2,177 stations are responsible for more than 2.1 trillion pounds of stationary air pollutants.*** This may actually be an underestimation: (a) a significant number of stations reported releases in a given year but failed to report in one or more subsequent years, (b) some stations only reported releases as small as 2 pounds, and (c) it may not include all compressor stations (e.g., non-Title V stations).

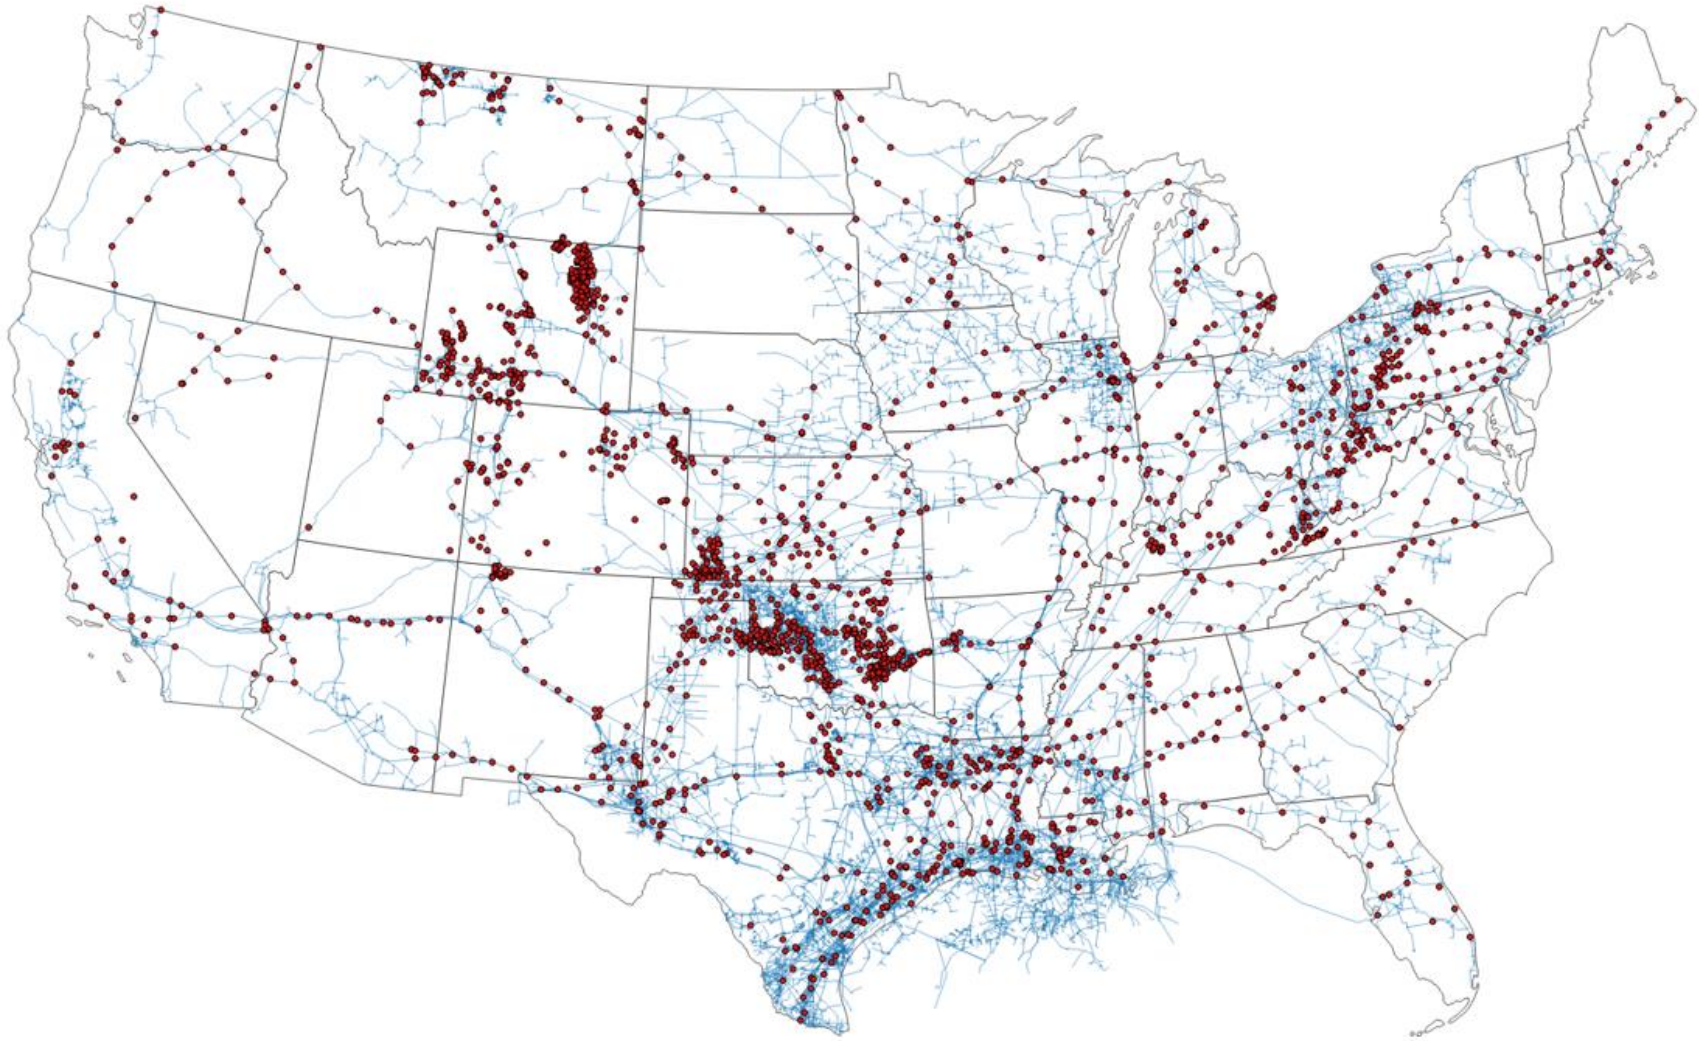

**Table 1.4.**

**U.S. National Gas Compressor Stations (NAICS Code 486210): 2,177**

## Table 1.4.

### U.S. National Gas Compressor Stations (NAICS Code 486210): 2,177

## 1.5. The Legal Framework for Accessing the Health and Environmental Risks of Natural Gas Compressor Stations

### 1.5.1. The Halliburton Loophole

The expansion of unconventional gas operations in the U.S. has largely occurred without benefit of the nominal health and environmental safeguards governing the siting and operation of oil and gas operations in force prior to 2004.

Under the terms of the Energy Policy Act of 2005, oil and gas operations were exempted from almost all existing federal air and water regulations.

The provision in the Act that exempts the oil and gas operations from federal rules covering all other industrial operations is the result of then Vice President Dick Cheney's Energy Task Force and is universally known as the "Halliburton loophole".

Halliburton Corporation is one of the three largest manufacturers of fracking fluids, making it one of the largest beneficiaries of the Act's disregard for even minimal health and safety concerns. Before becoming Vice President in 2001, Cheney was Halliburton's CEO.

In 1997 EPA was ordered to regulate hydraulic fracturing under the Safe Drinking Water Act (SDWA) by the U.S. Court of Appeals for the 11th Circuit (Atlanta), following the contamination of residential drinking water wells in Alabama. The Halliburton Loophole prohibits EPA from regulating the injection of fracturing fluids under the SDWA. In consequence, fracking wastewater is injected directly into or adjacent to underground drinking water without governmental oversight.

In response EPA undertook a 3-year study of the issue. Oil and gas industry representatives made up 5 of the 7 members of EPA's peer review panel, including a representative from Halliburton. The panel's findings, published in 2004, concluded that fracturing "poses little or no threat" to drinking water and that no further study of the question was necessary.

In its investigation, the transparently self-serving panel had ignored or concealed well documented evidence that fracking presents a significant threat to drinking water. Courageously, Weston Wilson, a 30-year veteran of the EPA in Denver, blew the whistle on the panel's violation of scientific principles and available evidence and the Agency's refusal to regulate what is clearly a hazard to public health. The weight of evidence in Wilson's charge that the panel's findings were "scientifically unsound" and the public outcry that followed, forced EPA inspector General Nikki Tinsley to conclude in March 2005 that there was sufficient evidence to justify a review of the panel's work.

It is at this point in the story that Cheney and his former employer Halliburton jumped into the breach--the passage of the Energy Policy Act effectively removed EPA from a meaningful regulation of fracking and related operations, not only of drinking water but also the terms of the Clean Water Act (CWA), the Clean Air Act, the Superfund Act, the Emergency Planning and Community Right-to-Know Act, and the National Environmental Policy Act.

### 1.5.2. Public Concerns about the Health Risks of Natural Gas Compressor Stations

The explosion in unregulated fracking operations made possible by the Halliburton Loophole has in turn resulted, as previously noted, in the expansion of natural gas compressor station operations and the constructions of thousands of miles of new pipelines.

As many knowledgeable observers have noted, existing federal, state and local policies that govern industrial site approval and the actual approval process fail adequately to protect the immediate and long-term health of the public or safeguarding the environment.

Many reasons account for this failure.

First and foremost is the view that development (“job creation”) is the paramount concern of government.

Policies certainly exist on paper stating that assessments of potential harm to public health and the environment are an integral part of the approval process.

In actual practice, these “safeguards” are largely a legal formality at great variance from governmental assurances that the primary concern is the public’s health and safety.

Only a small percentage of these proposals are rejected on grounds that they would unduly threaten public health and the environment; in most of these cases it is only because public interest groups could mount and sustain long legal and political struggles.

In the case of struggles attempting to prevent the construction of new or expansion of existing natural gas compression stations, they are waged without any quantitative assessment of potential immediate and long-term health risks associated with air emissions from these facilities.

When local officials or the public raise concerns about the potential health risks associated with natural gas compressor stations, the answer is always the same: “all required studies have been completed”.

What does this mean?

When an average person hears an “expert’s” confidently assertion that “all required studies have been completed”, they conclude this should be taken to mean it won’t cause immediate- or long-term damage to human health or the environment.

That, of course, is precisely the intention.

And to be truthful, this is what many people want to hear; they welcome such an assurance because it means the proposed plant is something they don’t have to worry about or spend time and effort organizing against.

The purpose of the assertion “all required studies have been completed” is to quell public doubt and to silence scientific criticism.

***The most important thing the public and local officials need to understand is that “all required studies have been completed” is not the same thing as saying (or the reality) that “there is no potential for increased risk of death or disease.”***

This is to say, the “required studies” do not, in our opinion, meaningfully protect human health.

The public works under the false assumption that the primary purpose of governmental regulations such as those under consideration is to determine what’s “safe”.

At best, such safeguards prevent egregious potential for harm, but often they don’t even do that.

There are several reasons for this.

The first is that preventing the public from any increased health risk is not the overriding goal of federal and state regulations. Rather, it is “balancing” potential harm from potential “benefits”.

This raises three obvious questions:

Who determines “the potential for harm”?

Who determines what constitutes a “benefit”?

And who determines what the balance between the two should be?

To state the obvious, it is not within the authority of the public, public health experts or independent scientific agencies to answer these questions.

The rules such as they are, have largely been written to advance the interests of industry even when public health and the environment are compromised. The case of the Halliburton Loophole is one obvious example. The refusal to take measures to address climate change is another.

Each of the 18 compressor stations analyzed in this report were required to complete 6 or more federal or state studies before they were given building permits. A few of these studies directly address health concerns, and in each case, they concluded that the proposed facility would meet governmental public health standards.

Let’s throw a few balls up in the air and try to juggle them.

*First ball:* As previously indicated, IARC has concluded that breathing outdoor air increases everyone’s risk of cancer, meaning that each and every minute of our lives we’re breathing a cocktail of chemical carcinogens.

*Second ball:* For more than 30 years EPA has maintained that any exposure to a known human carcinogen increases cancer risk.

*Third ball:* Based on data collected by the natural gas industry and reported by EPA, the 40.2 million pounds of pollution released by the state’s compressor in a 7-year period included 9.5 million pounds of carcinogens (83% of which were classified as “known human carcinogens” by one or more authoritative agency).

*Fourth ball:* All 18 compressor stations in NYS met all regulatory requirements and were granted building permits.

***If the air we breathe is already filled with hundreds of known human carcinogens, any exposure to a single carcinogen increases the risk of developing cancer and***

***compressor stations add 5.7 million pounds of carcinogens to the state's air every year, how can compressor stations not increase the risk of cancer?***

And is the assertion that “all required studies” fully protects public health in any meaningful sense plausible?

Anyone looking for an insight into the growing disillusionment of ordinary citizens with the regulatory process should attempt this logical juggling act.

### **Engineers and Industry Spokesmen Public Relations Posing as Public Health Experts**

It also needs to be understood that the industry spokesman and DEC officials attempting to assure the public that compressor stations pose no threat to human health, are almost without exception people who have no training in public health, epidemiology or toxicology.

In the case of industry representatives, they are public relations specialists or company spokesman who have memorized their lines.

And in the case of the DEC, they are well-qualified scientifically trained engineers with different areas of expertise, but this is not equivalent to being a scientifically trained medical or public health expert.

### **The NYS DOH**

It must also be recognized that historically DOH is reluctant to weigh in on such matters, preferring to let DEC carry the load.

In this connection, it's worth noting that we could locate no systematic analysis of compressor station pollution authored by the DOH.

The public only hears what engineers and public relations officials have to say on the health effects of compressor stations and natural gas pipelines (“all required studies have been completed”) and little or nothing from the agency specifically tasked with protecting public health.

## 1.6. The Precautionary Principle and Legal Damage Awards

In most cases legislative action to protect the public from the danger of chemical exposures generally only occurs long after harm has been done. This highlights the weakness of the existing approach to chemical regulation—if regulations were adequate there would not be so many effected populations.

Rather than waiting for harm to occur, progressive public health advocates believe regulation should be based on the precautionary principle --concept that when there is some evidence for harm from a particular exposure, but the level of evidence falls short of being clearly established, steps should none-the-less be taken immediately to reduce exposure. Study of hazards from environmental exposures often take many years for definitive results to be obtained, and if one waits to take action until you can count the bodies you will have unnecessarily harmed people. Furthermore, the latency for many diseases is long, and therefore if you take no steps to reduce exposure once the evidence becomes totally clear there will be people who have been unnecessarily exposure who will be developing diseases for many years to come.

Finally, in legal cases it is common for juries to award damages based on proof of exposure to a substance known to cause a disease such as cancer, even if that person does not have cancer him or herself. The level of proof of exposure is usually that the body burden of a substance, for example PCBs or dioxins, is significantly higher than most Americans (usually somewhere between the 75-95th percentile from NHANES). Therefore, courts accept the concept that exposure to a chemical that causes a known disease proves elevated risk of the disease even if the disease has not yet occurred.

## 1.2. The Existing Literature

### 1.2.1. Peer-reviewed studies of natural gas compressor stations

To the authors' knowledge, there are no peer-reviewed papers examining the health effects associated with pollutants generated by natural gas compressor stations.

PubMed (pubmed.gov), a free resource developed and maintained by the National Center for Biotechnology Information (NCBI) at the National Library of Medicine® (NLM), provided access to more than 27 million citations for biomedical and life science research. The search terms "compressor station" and "natural gas compressor" only generate 28 citations. Only 9 of the 28 have as the primary subject matter compressor stations. In the others, compressor stations are essentially a passing reference.

None provide a quantitative assessment of the volume of compressor station emissions, chemical content of these emissions or their potential health impacts.

Subject	Author
<b>Compressor Stations: major subject of the paper</b>	
Compressor stations, criteria pollutants	Goetz et al. 2015
Compressor stations, methane emissions	Jakober et al. 2014, Litto et al. 2012, Mayfield et al. 2017, Nathan et al. 2015, Subramanian et al. 2015
Compressor stations, ocular melanoma associated w\electric motor frequency	Milham and Stetzer 2017.
Compressor stations, operations, pipeline energy optimization	Liu et al. 2014
Compressor stations, operations, turbine improvement	Mohamed et al. 2016
Compressor stations, triaryl phosphate poisoning in cattle.	Beck et al. 2012
Compressor stations, vent operations	García et al. 2012
Compressor stations, wildlife impacts from noise	Bunkley, et al. 2017
Fracking operations, animal health	Bamberger and Oswald 2014
<b>Compressor Stations: passing reference</b>	
Fracking operations, chemical pollution	Brown et al. 2015, Hildenbrand et al. 2016, Pekney et al. 2014, Lan et al. 2015, Lavoie et al. 2015, Chepenko et al. 2012)

Natural gas operations, VOC emissions	Zielinska et al. 2015

#### 1.2.2. NYS DEC

The author could locate no specific statement reviewing the volume of releases of emissions from compressor stations, their content or the impact of these chemicals on human health on DEC's website.

#### 1.2.3. NYS DOH

In December 2014, NYS DOH published *A Public Health Review of High Volume Hydraulic Fracturing for Shale Gas Development* (NYSDOH 2014). The report provides a useful summary of peer-reviewed studies of the health impacts of unconventional gas development including compressor stations. To be precise, it contains 5 references to "compressor stations". But nowhere in this 186-page report is there a reference to the volume of emissions from compressor stations, their content or the impact of these chemicals on human health.

#### 1.2.4. National Academy of Science's Health Impact Assessment of Shale Gas Extraction

In 2014 the National Academy of Science published *Health Impact Assessment of Shale Gas Extraction: Workshop Summary* (NYAS 2014). The report contains a great deal of important information about the pollution associated with fracking but almost nothing concerning the pollution associated with the transportation of natural gas.

The phrase "compressor station" appears 13 times. None of these references provide any quantitative assessment of compressor station emissions.

But the last reference to compressor stations which appears in the report's final paragraph does say something quite important.

Finally, the panel was asked to comment on the testing of acute, short-term exposures versus low-level chronic exposures, for example, the low-level chronic exposures of farmers who leased out their land for hydraulic fracturing or homeowners who are living 100 feet from a compressor station and live with these emissions daily. The audience member noted that there has been remarkably little air and water testing in the U.S. gas fields to date, and the available testing efforts have shown exposures at "safe" levels, which is disheartening for people experiencing a multiplicity of health symptoms at these levels. . .

### 1.2.5. U.S. Environmental Protection Agency, Inspector General

A 2013 report from the United States Environmental Protection Agency 's Inspector General states that there is inadequate information available on direct measurement emissions from oil and gas production activities.

High levels of growth in the oil and natural gas (gas) production sector, coupled with harmful pollutants emitted, have underscored the need for EPA to gain a better understanding of emissions and potential risks from the production of oil and gas. However, EPA has limited directly-measured air emissions data for air toxics and criteria pollutants for several important oil and gas production processes and sources, including well completions and evaporative ponds. Also, EPA does not have a comprehensive strategy for improving air emissions data for the oil and gas production sector; the Agency did not anticipate the tremendous growth of the sector, and previously only allocated limited resources to the issue. (USEPA 2013)

### 1.2.6. U.S. Agency for Toxic Substances and Disease Registry

A 2016 report by the U.S. Agency for Toxic Substances and Disease Registry (ATSDR) of health particulate matter exposures in the vicinity of the Williams Central natural gas compressor station in Brooklyn Township, Susquehanna County, Pennsylvania, reached 2 fundamental conclusions:

**Conclusion 1, Short term exposures:** Exposure to maximum levels of PM<sub>2.5</sub> may be harmful to unusually sensitive populations, such as those with respiratory or heart disease, but are not at levels that are a concern to the general population.

**Conclusion 2, Chronic exposures:** The estimated annual average PM<sub>2.5</sub> concentration of 15 to 16 µg/m<sup>3</sup> may be harmful to the general population and sensitive subpopulations, including the elderly, children, and those with respiratory or heart disease.

(USATSDR 2016)

### 1.3. Requests for Information

The need for quantitative information about the volume of pollution and its potential to cause adverse health impacts has been the subject of resolutions by local governments, public health advocates as well as local, regional and state environmental organizations.

#### 1.3.1. Letter to Mr. Michael Higgins, NYS DEC, Division of Environmental Permits From the Westchester County Board of Legislators (February 2015)

Board of Legislators Resolution No. 80-2014 Resolution No. 80-2014 (“Resolution”) calls for independent, transparent, continuous and comprehensive baseline air testing to establish the public’s exposure to toxins that are currently being emitted from the compressor stations prior to allowing any increase in emissions. Furthermore, the resolution calls upon all involved agencies, including NYSDEC, to evaluate cumulative short and long-term health impacts of the entire proposed AIM project, including the impact of emissions from all regional sources of emissions, prior to any expansion of these compressor stations. (Westchester 2015)

#### 1.3.2. Letters to Governor Cuomo and Health Commissioner Howard A. Zucker From Concerned Health Professionals of New York, Physicians for Social Responsibility -- U.S., Physicians for Social Responsibility -- New York (October 14, 2015, May 29, 2014, February 27, 2013, October 4, 2012, March 16, 2012, December 12, 2011, October 5, 2011, March 26, 2011, February 28, 2011)

Compressor stations and pipelines are both major sources of air pollutants, including benzene and formaldehyde, that create serious health risks for those living nearby while offering little or no offsetting economic benefits. Compressor stations – used along regular intervals of most pipelines – in particular, are semi-permanent facilities that pollute the air 24 hours a day and expose nearby residents to levels of noise pollution known to induce negative health effects. Moreover, emerging data show that their day-to-day air emissions are highly episodic and create periods of potentially extreme exposures.

We have particular concerns about the air pollution events created by compressor station “blowdown” events, which are used for maintenance and to control pressure and can last for hours. The intentional or accidental releases of gas through valves create 30- to 60-meter-high gas plumes, causing high levels of contaminant release. Anecdotal accounts associate blowdowns with short term effects such as nosebleeds, burning eyes and throat, skin irritation, and headache. Given the chemicals released, we are deeply concerned about the possible long-term effects of these exposures, including cancer, asthma, heart disease and severe neurological impairments. We note that there exists neither a national nor a state inventory of compressor station accidents. We have yet to accumulate an extensive body of peer-reviewed research on the public health impacts of compressor stations, but our new report includes very troubling documentation of extensive leakage of methane and other contaminants. (CHPNY)

### 1.3.3. Letter to Mr. Christopher Hogan, NYSDEC, Division of Environmental Permits

---

From 14 NYS Physicians (September 12, 2016)

We are . . . greatly concerned that no state agency appears to be monitoring the ever increasing flow of information and scientific studies based on effects of UNGD and its associated infrastructure. On this point we would like to be mistaken; and please correct us if we are. But since the two-year Public Health Review of HVHF activities concluded in December 2014, it appears that DEC and DOH have “washed their hands” of the issue. Nevertheless, huge problems - with health impacts, quality of life and climate impacts associated with the proliferation of natural gas infrastructure in our state - are not going away. Someone needs to be paying attention to this, and “connecting the dots” - individual infrastructure projects must be considered not only separately but in their cumulative health, environmental, and climate impacts. We do not see this happening in New York State. (Medical Professionals 2016)

### 1.3.4. Public Statement: Mothers Out Front Mobilizing for a Livable Climate (Monroe County NY)

It is somewhat difficult to find scientific literature completely focused on the impacts of compressor stations. . . (MOF)

## 1.4. Summary of health effects

Based on data submitted by the natural gas industry and collected by DEC and EPA we show that 18 compressor stations in NYS were responsible for releasing more than 40 million pounds of toxic air pollutants over a 7-year period, including:

- 9.5 million pounds of human carcinogens,
- 18.8 million pounds of chemicals associated with blood and immune system disorders,
- 18.8 million pounds associated with endocrine, nutritional and metabolic disorders,
- 18.7 million pounds of chemicals with mental and behavioral effects,
- 18.7 million pounds that affect the brain and central nervous system,
- 24.7 million pounds that affect the eye and adnexa,
- 17.5 million pounds that affect the ear and mastoid process,
- 16.3 million pounds associated with circulatory system diseases including heart attacks and strokes,
- 39.6 million pounds linked to respiratory system diseases,
- 38.5 million pounds linked to digestive system diseases,
- 27.7 million pounds associated with skin and subcutaneous tissue disorders,
- 1.2 million pounds linked to musculoskeletal system and connective tissue diseases,
- 39.9 million pounds with genitourinary system diseases,
- 6.4 million pounds with urinary system diseases and disorders,
- 39.9 million pounds connected to pelvis, genital and breast diseases including reproductive disorders
- 19.6 million pounds that affect pregnancy, childbirth and the puerperium,
- 22.5 million pounds with certain conditions originating in the perinatal period,
- 39.6 million pounds with congenital malformations, deformations, chromosomal abnormalities, and
- 39.6 million pounds with symptoms, signs and abnormal clinical and laboratory findings, nec.

### **What should the public make of this?**

#### 1.4.1. A substantial amount of health relevant information is not reaching the public

A tenant of health and community governance is public information and health and safety. Community members depend on Public Officials to provide information needed to protect their health. In the case of gas compressor stations substantive amounts of health relevant information is not reaching the public. Instead of informing the public, the information is mired in bureaucratic processes.

#### 1.4.2. Governments' failure to analyze or communicate the results of its own data collection

The data analyzed in this report is collected by DEC and EPA. Neither agency has reported the total volume of pollution associated with the transportation of natural gas, let alone analyzed these releases in terms of how they potentially impact human health.

It is the responsibility of each compressor station in NYS to estimate the total volume of pollution they generate as well as its chemical constituents and to report this information to DEC--and they do.

DEC is required to review this information and forward it to EPA--and they do.

EPA assembles this data and make it available to the public, which they do, not just for compressor station but for millions of other sites nationally.

It is not the most difficult thing in the world to use the information collected and apply a little math. But, if either the EPA or DEC have ever done so, it is not something to our knowledge that has been presented to the public. Nor have we found this information on their respective web sites.

The information that is collected is presented in formats that are not readily understood by local residents. To be useful, the most important conclusions and insights of technical data must be comprehensible to the average person.

#### 1.4.3. DOH's failure to analyze the potential health impacts of compressor station pollution

For its part, even if EPA and DEC are not interested in analyzing the compressor station emission data they collect, there is nothing to prevent DOH from doing so.

DEC\EPAs' compressor station data is publicly available. DOH could download it and do the math.

Again, as far as the authors are aware, DOH has not done so.

#### 1.4.4. Industry and governmental assurances that gas compressor stations “comply with all air quality requirements” and that they therefore pose no unreasonable threat to public health

Each of the 57 compressor stations that have been permitted by DEC have been approved based on the conclusion that they comply with all federal and state air quality requirements.

When members of the public or local officials question the potential health effects of compressor station pollution, the response from industry, EPA, DEC and DOH is always that “all legal requirements have been met” -- the clear implication being that if these “legal requirements” have been met, there is no reason to be concerned about adverse health effects.

For example, in a public statement issue by Dominion Transmission concerning its New Market Project, it states: “The FERC approved New Market on April 28, 2016 after 23 months of evaluating all environmental, health and safety concerns associated with the project.”

Dominion poses the question, “What will be the environmental and public health concerns?”

Its answer:

Any emissions from the compressor station will comply with all air quality requirements, which are established to protect the public health, safety and welfare. We would not operate the compressor station if we could not operate it according to stringent air quality regulations.

Ensuring compliance with environmental requirements fall either to the Environmental Protection Agency (EPA) or state environmental agencies (states by delegation), depending on the specific permit and rule. (Dominion 2016)

Dominion is disingenuous. Their health and safety officials recognize, or should recognize, that Federal and State Environmental laws and regulations are designed to protect the general health of regional populations and not to protect any single group of locally exposed persons. The “stringent air quality regulations” that Dominion refers to are those established by EPA for the purpose of controlling regional levels of pollution and even in this limited context these regulations fail to protect the public from all manner of demonstrably harmful exposures.

Therefore, these regulations make three critical, scientifically questionable assumptions when applied to local pollution.

The “stringent air quality regulations” that Dominion refers to are those established by EPA.

It is beyond the scope of this project to provide a full analysis of this claim, but several brief observations are in order.

First, the regulation used to determine the potential health impacts of chemical exposure make three critical, scientifically questionable assumptions.

##### 1. Individual Chemicals versus Chemical Mixtures

First, it effectively assumes that an air standard can be set for a single chemical to protect against unnecessary risk. The problem here is that setting standards for individual chemicals makes very little sense when people are continuously exposed to multiple complex chemical mixtures.

The mixture of any two chemicals can be additive ( $1 + 1 = 2$ ), less than additive ( $1 + 1 = 1.5$ ), or synergistic ( $1 + 1 = 2+$ ).

NYS's national gas compressor stations reported releasing more than 70 chemicals.

This number includes 31 chemicals associated with circulatory diseases like heart attacks and strokes. Knowing how much risk is associated with a single circulatory toxicant tells us nothing about the real-world risk of being exposed to 31.

The state's compressor station reported releasing a total of 59 carcinogens, including 23 chemicals classified as "known human carcinogens" by an authoritative international, federal or state agency. Of the 9.6 million pounds of carcinogens released from 2008 to 2014, 83% were known to cause cancer in humans. The effect of being exposed to multiple carcinogens is not considered in EPA or DEC regulations.

## **2. Average versus Acute Exposures**

EPA and DEC guidelines assume that the exposures from a facility occur evenly over time. In fact, for any given facility air pollution releases fluctuate widely. What this means is that at times of peak exposure individuals may breathe chemical concentrations greater than what is assumed to be safe. Studies have shown that levels of the carcinogens formaldehyde, benzene and 1,3-butadiene periodically exceed what federal and state guidelines consider safe at natural gas compressor stations in four states. (Macey et al. 2014).

## **3. Healthy versus health-compromised or particularly vulnerable populations**

With a few exceptions, EPA and DEC guidelines assume that everyone is at equal risk from the harmful effects of air pollution. This is simply not the case. There are many populations who are at greater risk, including, infants, children, pregnant women, the elderly, those with compromised immune systems, and those already suffering from specific diseases or disorders.

Studies have shown that the cancer rates are proportional to levels of regional air pollution. These three points aside, it is plausible that the release of 9.6 million pounds of carcinogens in a 7-year period, and continued releases over the active use of the facility does increase the incidence of certain types of cancer.

When national economic concerns are given priority higher than community health it is necessary to provide simple and clear guidance to the person whose risk is increased. In those situations, it is not appropriate to compare risks to other sources or situations. Individuals who know that they are of enhanced risks, avoid polluted areas.

The environmental and health risks can be handled much more fairly. To do so requires recognition of commonly understood concepts and readily accessible information.

## **4. Other general concerns**

Problems associated with risk assessments broadly understood and air pollution standards have been identified by a number of researchers (Goodman et al. 2013, Maynard et al. 1995, McClellan 2012, Mauderly et al. 2010.)

#### 1.4.5. The absence of concrete information about potential health impacts in industry proposals

In the proposals we have reviewed, there is an absence of concrete information about exposures and their potential health impacts.

Millennium's proposal for its Highland Compressor Station is a case in point.

In July 2016, the company submitted its application proposal, *Millennium Pipeline Company, LLC Highland Compressor Station, Eastern System Upgrade Project, Air State Facility Permit Application* to regulators.

The 83-page report contains a great amount of important information but almost nothing substantive about potential adverse human health impacts.

A search of the document shows that the word "health" only appears four times

First, as a footnote to table **Table 2-1: Proposed Facility Emissions (tons/year)**.

(3) Trivial per 201-3.3(94) for emissions of "...oxygen, carbon dioxide, nitrogen, simple asphyxiants including methane and propane, trace constituents included in raw materials or byproducts, where the constituents are less than 1 percent by weight for any regulated air pollutant, or 0.1 percent by weight for any carcinogen listed by the United States Department of **Health** and Human Services' Seventh Annual Report on Carcinogens (1994). The definition of "regulated air pollutant" under 200.1(bu) does not include methane or ethane.

Second, in section **3.4.1 Exempt and Trivial Sources**, the same sentence is repeated.

Blowdowns are considered a trivial activity per 6 NYCRR 201-3.3(94) which covers "Emissions of the following pollutants: water vapor, oxygen, carbon dioxide, nitrogen, inert gases such as argon, helium, neon, krypton and xenon, hydrogen, simple asphyxiants including methane and propane, trace constituents included in raw materials or byproducts, where the constituents are less than 1 percent by weight for any regulated air pollutant, or 0.1 percent by weight for any carcinogen listed by the United States Department of **Health** and Human Services' Seventh Annual Report on Carcinogens (1994)." The natural gas composition at the Highland Station meets the definition in 6 NYCRR 201-3.3 as shown in Appendix B.

Third, in section **3.6 New York State Department of Environmental Conservation Regulations:**

If the agency considers that any project triggering minor NSR permitting could threaten attainment with the National Ambient Air Quality Standards (NAAQSs) or human **health** from toxic air pollutant (TAP) concentrations, NYSDEC can require air dispersion modeling for the Project. A site wide modeling analysis for criteria pollutants has been performed in accordance with their impact analysis modeling guidance, Policy DAR-10. In addition, a modeling analysis that addresses TAPs is performed per Policy DAR-1. This section details the NAAQS and TAPs modeling assessment for the proposed Highland Station.

And fourth, as an unchecked box in Rule Citation 201-3.2(c), item 20, "Municipal/Public **Health** Related."

A subsequent report by the company, Millennium Pipeline Company, LLC, Eastern System Upgrade Project, Hancock and Highland Compressor Stations, Human Health Risk Assessment (February 2017), addresses health concerns more explicitly. But, again, there is (a) no attempt to place compressor station pollutants within the context of the overall burden of pollution in NYS or (b) explicit discussion of the what the peer-reviewed science has to say about the potential health effects of releases.

## 1.6. Other sources of exposure to the 70 chemicals released by natural gas compressor stations

In the course of a single day each of us is exposed to hundreds of toxic chemicals. Over a lifetime, the number is in the thousands or, more probably, tens of thousands.

It is often assumed, mistakenly in our view, that continuous exposure to high levels of toxic chemicals are required to produce illness. In fact, illness may result from a small exposure, especially if exposure occurs continuously over time.

Compressor stations represent a significant source of airborne pollution in NYS, increasing the likelihood of disease, particularly for local communities. The potential health effects of compressor stations are clearly a principal concern for communities opposing their construction or expansion. As we try to show in these pages, the potential for harm is real and their concern justified. At the same time, it's necessary to not lose sight of the forest when we're looking at the trees. Pollution from compressor stations is a significant threat to human health, but it is one of many. All need to be understood and addressed.

A few essential facts:

- Each year the U.S. manufactures or imports trillions of pounds of chemicals. Of the 70 chemicals released as combustion pollutants from natural gas compressor stations, 27 are produced at a volume of more than 1 million pounds annually in the U.S. Of this number, 13 are produced at more than 1 billion pounds and 3 at more than 10 billion pounds. (Given the limitations of EPA's reporting on chemical manufacturing and importation, these numbers are in all probably underestimations.)
- Companies don't manufacture or import chemicals with the intention of creating pollution but to use them in products. In the course of **production**, a relatively small percentage of chemicals are released into the environment. In absolute numbers, of course, the volume of air and water pollution released and hazardous waste generated is extraordinary, but the most significant source of pollution occurs **after production**, when chemicals incorporated into products and are used and in many cases, discarded. The single most important source of airborne pollution in the U.S. is the combustion of gasoline and diesel fuel in on-road vehicles. At present, the U.S. has 139 operating petroleum refineries, located in 39 states. Eighty-nine are located just four states: Texas, California, Oklahoma, and Louisiana, and these account for more 10 million of the 16.7 billion barrels produced daily. Studies consistently find extremely high levels of air and water pollution and significantly higher rates of human disease around refineries. But far more pollution is created and more people are exposed to its harmful effects when the 7 billion barrels of petroleum produced each year in the U.S. are used, most notably, when they are burned in cars, trucks, buses and planes or used as fuel for heat or electricity generation.
- Prior to EPA's creation in 1970, there was literally no national regulation of chemical production or chemical waste disposal and only the flimsiest air and water pollution regulations. In 1970, an estimated 65,000 chemicals were in use in the U.S. EPA "grandfathered" these chemicals, meaning that companies could continue to use them until the Agency had time to determine if their use should be continued. New chemicals would have to be approved for use by EPA prior to introduction, but they didn't have to be tested. Nearly a half century later, more 85,000 chemicals have now been approved for use by EPA under Toxic Substances Control Act (TSCA), but fewer than 1,000 have been systematically

evaluated for their potential to harm human health and the environment by a federal agency (EPA and NTP), and only a small number have been withdrawn from use.

- Even when a chemical is clearly shown to present significant harm to human health or the environment, it is extremely difficult to have its use terminated. The fact that a chemical has been shown to be a known human carcinogen does not, for example, mean its use is automatically prohibited or restricted. This only happens in the rarest of circumstances and only longer after the problem has been documented. The current controversy concerning chlorpyrifos, a pesticide known to affect childhood brain development, is a case in point.
- Of the estimated 85,000 chemicals approved for use in the U.S. by EPA, fewer than 1,500 are systematically tracked as environmental pollutants or as food and water contaminants. Of this number, fewer than 900 are tracked as air pollutants.
- Of the 319 chemicals in EPA National Emissions Inventory, 198 were reported as air pollutants in NYS in the period from 2008 to 2014, meaning the state's residents were exposed to 128 additional chemicals not related as compressor station releases.
- The 70 chemicals released as compressor station stack air pollutants can be found in many other point sources or air pollution reported by NEI. These same 70 chemicals are reported as non-point sources by NEI, and 40 as on-road and non-road sources. Thirty-five of these 70 chemicals are residential air pollutants.
- Forty-one of the 70 chemicals released as compressor station stack can be found in clothing and textiles, jewelry, personal care products, cosmetics, perfumes, skin, hair care products, hair dyes, shoes and leather products, tobacco products/smoking.
- Forty-four of the 70 chemicals released as compressor station stack pollutants can be found on food items.
- In recent years CDC's NHANES has studied the number of chemical contaminants found in our bodies. These studies and those of the Environmental Working Group (EWG) have shown that chemical contaminants found in our bodies are varied as are their potential health impacts., and that even those working in relatively "clean" occupations also suffer significant contamination. Perhaps the most startling finding is that chemical contamination occurs before births. Dozens of toxic chemicals can be found in umbilical cord blood or placenta, including many chemicals known or suspected of causing human cancer.

Of the 70 chemicals released as compressor station stack pollutants, 48 are documented body burden contaminants, including: blood (29), breast milk (17), umbilical cord (20), placenta, sweat (3), urine (11), and unspecified (1).

- Air Pollution \ Cancer
  - Outdoor air is a known human carcinogen. (IARC)
  - In 2005, nearly all U.S. children (99.9%) lived in census tracts in which hazardous air pollutant (HAP) concentrations combined to exceed the 1-in-100,000 cancer risk benchmark. (US EPA)
  - 7% of children lived in census tracts in which HAPs combined to exceed the 1-in-10,000 cancer risk benchmark. (US EPA)
- Air Pollution \ Non-neoplastic diseases (health effects other than cancer)
  - 56% of children lived in census tracts in which at least one HAP exceeded the benchmark for health effects other than cancer. (U.S. EPA)

- In 2015, 59% of U.S. children lived in counties with measured pollutant concentrations above the levels of one or more national ambient air quality standards. (U.S. EPA)

- Drinking Water \ Health Standards
  - In 2015, approximately 7% of children served by community drinking water systems that did not meet all applicable health-based standards. (U.S. EPA)
  - Between 1993 and 2015, the estimated percentage of children served by community water systems that had at least one monitoring and reporting violation fluctuated between about 10% and 21%, and was 12% in 2015. (U.S. EPA)
- Drinking Water \ Detectable organophosphate pesticide residues (U.S. EPA)
  - In 2009, 35% of sampled apples
  - In 2007, 5% of sampled carrots
  - In 2008, 9% of sampled tomatoes
  - In 2009, 8% of sampled grapes
- Hazardous Waste
  - As of 2009, approximately 6% of all children in the United States lived within one mile of a Corrective Action or Superfund site that may not have had all human health protective measures in place, disproportionately affecting more Black children. (U.S. EPA)

## 1.7. President's Obama's Cancer Panel

These specific points aside, it's useful to consider the claim that environmental pollution from natural gas compressor stations poses no threat to human health in the context of the findings of the President's Cancer Panel (2010).

Between September 2008 and January 2009, the President's Cancer Panel (PCP) convened four national meetings "to assess the state of environmental cancer research, policy and programs addressing known and potential effects of environmental exposure on cancer."

The Panel's report, released in 2010, came to this essential conclusion:

"Research on environmental causes of cancer has been limited by low priority and inadequate funding. . . There is a lack of emphasis on environmental research as a route to primary cancer prevention. . . Cancer prevention efforts have focused narrowly on smoking, other lifestyle behaviors and chemo-preventive interventions. Scientific evidence on individual and multiple environmental exposure effects on disease initiation and outcomes, and consequent health system and societal costs, are not being adequately integrated into national policy decisions and strategies for disease prevention, health care access and health system reform." (U.S. DHHS 2010)

In the light of Panel's conclusion, the results of our study raise three significant questions:

First, what percentage of cancers is likely a consequence of exposure to chemical carcinogens?

Secondly, what is the impact of occupation as compared to non-occupation exposures?

Finally, how adequate are policies that both inform people of hazards and act to reduce exposure to chemical carcinogens?

There is considerable debate on the question of what percentages of cancers are due to exposure to chemical carcinogens, both in the workplace and elsewhere. Doll and Peto (1981) "provisionally estimated" that 4% of cancer was due to occupational exposures, but attributed most of this to lung cancer. Mokdad et al. (2004) ascribed only 2.3% of causes of death in the US to "toxic agents", but then attributed 18.1% to tobacco and 16.6% to poor diet and physical inactivity, not distinguishing the degree to which either was due to chemicals in tobacco or food. Schottenfeld et al. (2013) list tobacco, alcohol, ionizing radiation, solar radiation, infectious agents and obesity as risk factors for cancer, but totally ignore other chemical carcinogens other than occupational exposures. Prüss-Ustün and colleagues from the World Health Organization (2016) attribute 19% of all cancer to environmental factors, which includes 2-8% due to exposure in occupational exposures. Their report does not consider smoking, alcohol, diet or genetic factors. In discussing specific cancers, they attributed colon and rectal cancer to low physical activity, radiation and asbestos, but do not mention other chemical carcinogens in food. Chemical exposure is identified as a risk factor for breast, lymphoma, multiple myeloma, leukemia, larynx, bladder and melanoma cancers. Clapp et al. (2008) note that while overall cancer rates are declining (especially lung among men and colorectal in both sexes), some are rising (esophagus, liver, thyroid, melanoma, non-Hodgkin's, multiple myeloma, testicular, bladder, brain, and lung in women). Childhood cancers (leukemia and brain) are also rising. They and Belpomme et al. (2007) provide strong evidence that exposure to carcinogenic chemicals plays a major role in risk of these cancers. Christiani (2011) has suggested that 85-95% of cancer arise because of exposure to specific carcinogenic agents.

In addition to exposure to chemical carcinogens, cancer can be caused by genetics, infection and inflammation. Lichtenstein et al. (2000) reported an analysis of mono- and di-zygotic twins in Scandinavia in an effort to distinguish genetic from environmental factors in causation of cancer. They concluded that most cancers were due to environmental factors. Genetic factors were relatively unimportant in most cancers, although were significant in prostate (42%), colorectal (35%) and breast cancer (27%). Wu et al. (2016) examined intrinsic and extrinsic risk factors for cancer, and concluded that intrinsic factors contribute only modestly (less than 10-30%) to the risk. This is not to imply that individual genetic differences are unimportant, because polymorphisms of drug metabolizing enzymes serve as modulators of cancer susceptibility (Taningher et al., 1999).

These reports indicate that we do not have good understanding of the relative role of exposure to chemical carcinogens in overall cancer incidence beyond general knowledge that many chemicals to which humans are exposed cause cancer. Clearly carcinogenic chemicals are found in both the occupational and non-occupational environment. While the chemical exposure in an occupational setting differs from that of the general population, there are many carcinogens found in food, tobacco, personal care products, and indoor and outdoor air. Many use terms such as “life-style” to encompass such behaviors, without considering the carcinogenic chemicals that result from these behaviors. Workers have all of these non-occupational exposures as well as those specific to the workplace.

EPA’s official policy is that exposure to any level of carcinogen increases the risk of cancer. At the same time, EPA has a methodology to determine the extent of risk that rarely finds excessive risk. It is hard to fathom how the release of 9.6 million pounds of carcinogens in a 7-year period does not increase the incidence of cancer.

## Chapter 2. Compressor Station Releases

This page intentionally blank.

2.1. Number, Categorization and Operational Status of Facilities

This report analyzes the emissions data for 18 natural gas compressor stations in New York State (NYS) as reported to the National Emissions Inventory (NEI) of the U.S. Environmental Protection Agency (EPA) as point sources of air pollution for the period 2008 to 2014.

The author could not locate a single list of facilities involved in the storage and transportation of natural NYS from either state or federal sources.

One was created by reviewing all DEC air permits and identifying those that are compressor stations and comparing it to those listed in EPA’s Envirofacts System.

This is a little more complicated than it might seem because there are a large number of permits and permit modifications, all compressor stations are not necessarily labeled as such, there are apparent inconsistency in NAICS and SIC classifications, and some sites have multiple functions.

We identified a total of 58 compressor stations, including operational (55), approved (2), denied (1), and pending (3).

This list provides what the author believes is an accurate characterization of major natural gas facilities in NYS but it should not be considered comprehensive or final. Additional research would undoubtedly identify additional sites, especially minor ones, and clarify the function of several sites.

Table 2.1

Facility Type	Total
Compressor stations	58
Operational	55
Proposed: Approved	2
Proposed: Denied approval	1
Dehydration facility	1
Gas turbine facility	4
Gate	3
Holding point tap	2
Metering & regulation station	19
Pig launching or receiving	1
Storage & filling	1
Unknown	2

## 2.2. NYSDEC Air Pollution Control Permits and Registrations

Under the Clean Air Act and under New York State law and regulation, most notably 6 NYCRR Part 201, NYSDEC is required to issue permits for polluters. The two most common permits for large on-site polluters are: “Air Title V Facility permits” and “State facility permits”.

NYSDEC describes these as follows:

### 2.2.1. State Facility Permits

State facility permits are issued to facilities that are not considered to be major (as defined in the department's regulations), but that meet the criteria of Subpart 201-5. ([link leaves DEC](#)) These are generally large facilities with the following characteristics:

- Their actual emissions exceed 50 percent of the level that would make them major, but their potential to emit as defined in 6NYCRR Part 200 does not place them in the major category
- They require the use of permit conditions to limit emissions below thresholds that would make them subject to certain state or federal requirements
- They have been granted variances under the department's air regulations, or
- They are new facilities that are subject to New Source Performance Standards (NSPS) or that emit hazardous air pollutants. Instead, all DEC site.

### 2.2.2. Title V Permits

Title V facility permits, the second type of permit, are issued to facilities subject to Subpart 201-6. These include facilities that are judged to be major under the department's regulations, or that are subject to New Source Performance Standards (NSPSs), to a standard or other requirements regulating hazardous air pollutants or to federal acid rain program requirements.

Title V permits reduce violations of air pollution laws and improve enforcement of those laws by:

- Recording in one document all of the air pollution control requirements that apply to the source. This gives members of the public, regulators, and the source a clear picture of what the facility is required to do to keep its air pollution under the legal limits.
- Requiring the source to make regular reports on how it is tracking its emissions of pollution and the controls it is using to limit its emissions. These reports are public information, and you can get them from the permitting authority.
- Adding monitoring, testing, or record keeping requirements, where needed to assure that the source complies with its emission limits or other pollution control requirements.
- Requiring the source to certify each year whether or not it has met the air pollution requirements in its title V permit. These certifications are public information.
- Making the terms of the title V permit federally enforceable. This means that EPA and the public can enforce the terms of the permit, along with the State.

(Source: NYSDEC)

The legal intention of a Title V operating air permit is described by DEC as:

The Title V operating air permit is intended to be a document containing only enforceable terms and conditions as well as any additional information, such as the identification of emission units, emission points, emission sources and processes, that makes the terms meaningful. 40 CFR Part 70.7(a)(5) requires that each Title V permit have an accompanying "...statement that sets forth the legal and factual basis for the draft permit conditions". The purpose for this permit review report is to satisfy the above requirement by providing pertinent details regarding the permit/application data and permit conditions in a more easily understandable format. This report will also include background narrative and explanations of regulatory decisions made by the reviewer. It should be emphasized that this permit review report, while based on information contained in the permit, is a separate document and is not itself an enforceable term and condition of the permit.

### 2.2.3. Changing permit status over time

A facility's permit status can change over time.

A station initially permitted with a permit type "Air State Facility" may subsequently seek site expansion or modifications which DEC may determine requires a "Title V" permit, or the reverse might be true.

To determine the present status of a particular station, see NYS DEC air permits:

**Issued Title V Permits**

## 2.3. Reporting Requirements for Compressor Stations with Title V Permits

Each permitted point-source of pollution must meet one or more state or federal reporting requirements.

The two tables which follow summarize the principal air pollution regulatory programs applicable for each of the 18 NYS compressor stations under review.

Table 2.3.1.

## Applicable State and Federal Air Pollution Regulatory Programs: Summary

## NYS Natural Gas Compressor Stations

Regulatory Program	Description	No
<b>Prevention of Significant Deterioration</b> <b>PSD</b> <b>40 CFR 52</b>	Prevention of Significant Deterioration (40 CFR 52) - requirements which pertain to major stationary sources located in areas which are in attainment of National Ambient Air Quality Standards (NAAQS) for specified pollutants.	4
<b>New Source Review</b> <b>NSR</b> <b>6 NYCRR Part 231</b>	New Source Review (6 NYCRR Part 231) - requirements which pertain to major stationary sources located in areas which are in non-attainment of National Ambient Air Quality Standards (NAAQS) for specified pollutants.	0
<b>National Emission Standards for Hazardous Air Pollutants</b> <b>NESHAP</b> <b>40 CFR 61</b>	National Emission Standards for Hazardous Air Pollutants (40 CFR 61) - contaminant and source specific emission standards established prior to the Clean Air Act Amendments of 1990 (CAAA) which were developed for 9 air contaminants (inorganic arsenic, radon, benzene, vinyl chloride, asbestos, mercury, beryllium, radionuclides, and volatile HAP's).	0
<b>Maximum Achievable Control Technology</b> <b>MACT</b> <b>40 CFR 63</b>	Maximum Achievable Control Technology (40 CFR 63) - contaminant and source specific emission standards established by the 1990 CAAA. Under Section 112 of the CAAA, the US EPA is required to develop and promulgate emissions standards for new and existing sources. The standards are to be based on the best demonstrated control technology and practices in the regulated industry, otherwise known as MACT. The corresponding regulations apply to specific source types and contaminants.	14
<b>New Source Performance Standards</b> <b>NSPS</b> <b>40 CFR 60</b>	New Source Performance Standards (40 CFR 60) - standards of performance for specific stationary source categories developed by the US EPA under Section 111 of the CAAA. The standards apply only to those stationary sources which have been constructed or modified after the regulations have been proposed by publication in the Federal Register and only to the specific contaminant(s) listed in the regulation.	7
<b>Title IV Acid Rain Control Program</b> <b>Title IV</b> <b>40 CFR 72-78</b>	Title IV Acid Rain Control Program (40 CFR 72 thru 78) - regulations which mandate the implementation of the acid rain control program for large stationary combustion facilities.	0
<b>Title V</b>		18
<b>Title VI Stratospheric Ozone Protection</b> <b>Title VI</b> <b>40 CFR 82, Subparts A-G</b>	Title VI Stratospheric Ozone Protection (40 CFR 82, Subparts A thru G) - federal requirements that apply to sources which use a minimum quantity of CFC's (chlorofluorocarbons), HCFC's (hydrofluorocarbons) or other ozone depleting substances or regulated substitute substances in equipment such as air conditioners, refrigeration equipment or motor vehicle air conditioners or appliances.	0
<b>Reasonably Available Control Technology</b> <b>RACCT</b> <b>6 NYCRR Parts 212.10, 226, 227-2, 228, 229, 230, 232, 233, 234, 235, 236)</b>	Reasonably Available Control Technology (6 NYCRR Parts 212.10, 226, 227-2, 228, 229, 230, 232, 233, 234, 235, 236) - the lowest emission limit that a specific source is capable of meeting by application of control technology that is reasonably available, considering technological and economic feasibility. RACT is a control strategy used to limit emissions of VOC's and NOx for the purpose of attaining the air quality standard for ozone. The term as it is used in the above table refers to those state air pollution control regulations which specifically regulate VOC and NOx emissions.	18
<b>State Implementation Plan</b> <b>SIP</b> <b>40 CFR 52, Subpart HH</b>	State Implementation Plan (40 CFR 52, Subpart HH) - as per the CAAA, all states are empowered and required to devise the specific combination of controls that, when implemented, will bring about attainment of ambient air quality standards established by the federal government and the individual state. This specific combination of measures is referred to as the SIP. The term here refers to those state regulations that are approved to be included in the SIP and thus are considered federally enforceable.	18

## 2.4. U.S. EPA NEI Reporting for Compressor Stations

How a facility is permitted determines how its pollution data is tracked by NEI.

Compressor stations receiving a “Title V” permit are tracked by the system NEI uses for point air pollution sources. Compressor stations receiving a “State Facility Permit” are tracked by the system NEI uses for non-point sources of air pollution.

There is one exception: A single station with a “State Facility Permit” is being tracked as an NEI on-site polluter. It is unclear why this is the case.

### 2.4.1. Compressor Stations with a “Title V Permit”

The NEI for 2008-2014 includes data for 18 compressor stations in NYS.

There are, however, several additional sites classified as “Title V” facilities on the DEC’s website which are not found in NEI. (We notified DEC of this discrepancy and are in conversation to determine why these sites are not included as NEI point polluters. The compressor sites found in NEI are the exclusive source or data for this report.)

North American Industry Classification System (NAICS) code 48621 is used to designate facilities whose main purpose is the transportation of natural gas. Each of the 18 sites analyzed have this classification.

### 2.4.2. Compressor Stations with a “State Facility Permit”

We have identified 19 non-Title V compressor stations which, based on federal and state guidelines, should be reported as non-point NEI sources. Because these stations are not easily identified within NEI and the time limits and scope of this project, an analysis of the pollution associated with their operation is not included in this report.

Table 2.4.2.

### NYS Compression Station Releases by Facility: Total Pounds: 2008-2014

# New York's 59 Compressor Stations

### 2.5c.1. Releases by Facility: Circular Area Air Pollution Profiles

Because most compressor stations are located in sparsely populated areas, it is widely believed that relatively few people are directly exposed to their air releases. An examination of actual population counts by distance from each station, reveals a more complex picture. While it is true that only 2,660 people live within ½ mile of the 18 compressor stations analyzed in this report, nearly 1.7 million live within 10-mile radius—more than 1 out of every 8 New Yorkers.

Table 2.5c.1a.

At a given site the concentrations of pollutants is largely directly dependent on local emissions, but there are many important exceptions to this general rule.

In this connection, the most important fact to bear in mind is that ***human illness or an adverse environmental effect is not necessarily the result of the preponderance of pollutants in a place but may be caused by a single pollutant which may have traveled great distances and that relatively small quantities can be extremely dangerous.***

As we have already indicated, the distance air pollution travels and how much reaches ground level is dependent on many factors. On any given day, pollution from a given site can travel less than a mile, a few miles, hundreds of miles, thousands of miles, or around the globe.

A few local examples.

### Chernobyl disaster

The meltdown of the Chernobyl nuclear power plant in the Ukraine on April 26, 1986, released 100 times more airborne radiation than the fallout from U.S. nuclear bombs dropped on Hiroshima and Nagasaki. More than 40% of Europe's land mass to the north and west and had measurable amounts of radiation contamination, including Austria, Belarus, Bulgaria, Finland, France, Germany, Great Britain, Greece, Iceland, Italy, Norway, Romania, Slovenia, Sweden, and Switzerland, wide territories to the south including Armenia, Georgia, northern Africa and the Emirates, and China to the west. By May 6<sup>th</sup>, contamination reached Canada and the U.S. – more than half-way around the globe. (Yablokov and Nesterenko 2009, Gould 1990). The conclusion reached by the UN Scientific Committee on the Effects of Atomic Radiation is that the Chernobyl disaster "Resulted in radioactive material becoming widely dispersed and deposited . . . throughout the northern hemisphere." And that "[r]eleases of radioactive materials were such that contamination of the ground was found to some extent in every country in the Northern Hemisphere." (UNSCEAR 2011). Measurable amounts of Iodine-131 from Chernobyl fallout were found in fresh milk (Feely et al. 1988) and New York City's air along with Cesium-137 (U.S. DOE 1986), total ground deposition of Iodine-131 and Cesium-137 in Chester, New Jersey (U.S. DOE 1986), and gross beta particles in precipitation in Montpelier, Vermont (U.S. EPA 1986).

### Fallout from U.S. Nuclear Weapons Tests: Rochester and Troy NY

At dawn on July 16, 1945 in the dessert of Alamogordo, New Mexico, America exploded the world's first atomic weapon, code named "Trinity". Over the next few weeks Eastman Kodak headquarters were flooded with complaints from customers who had purchased sensitive X-ray film that it had been rendered unusable due to "fogging". Within a few weeks the company's scientists had determined that the strawboard, used as a stiffener board between film sheets produced in mills in Vincennes, Indiana had been contaminated "a new type radioactive containment not hitherto encountered." This, in turn, had produced black exposed spots on the company's film.

Alerted to the danger of open-air testing of nuclear weapons, Kodak began routinely measuring ambient radioactivity. In late January 29, 1951, the company's Geiger counters measured elevated levels of radioactivity brought to the ground by

a winter snow storm. The radiation was the result of a 1-kiloton nuclear test that had taken place in Nevada two days earlier. On February 3, the *New York Times* ran a front-page story on the incident, highlighting the work of University of Rochester scientists who had quantified trace amounts of radioactivity in the city's snow. (Mehmott 2016)

On April 28, 1953, the Geiger counters of Rensselaer Polytechnic Institute chemistry professor Herbert Clark began crackling away at surprising high levels. A severe rainstorm had brought down radiation from a nuclear test that had occurred three days earlier in the Nevada desert. The blast from the 11,000-lb. nuclear bomb code-named Simon had risen to a height of 44,000 feet above sea level, where 115 miles an hour winds carried it to Troy, some 2,300 miles downwind in just a few days. Levels of radioactivity in drinking water measured the next day were 100 to 1000 times greater than natural background radioactivity. (Clark 1954, Lade 1953, Lade 1962, Heller 2003).

### Depleted Uranium Contamination: Albany and Colonie NY

From the late 1950s through 1980, the National Lead company and the U.S. government operated a facility on Central Avenue in Colonie, New York, that fashioned depleted uranium (DU) for use in U.S. armor-piercing shot and shell, and in the process exposed its workforce and nearby residents to significant levels of radioactive contaminants. During its years of operation there no efforts were made to systematically monitor air, soil, surface water or groundwater for excessive contamination at either the 18-acre work site or in the community where the plant was located. More than 20 years after the plant closed, researchers found measurable levels of DU among former workers and Colonie residents (Parrish et al. 2008). But DU contamination was not confined to National Lead property or even the nearby neighborhood of Roessleville. In the 1990s, air filters at Knolls Atomic Power Laboratory in Niskayuna, about 3.5 miles away, detected DU from National Lead. Even more alarming is that more than 25 miles away DU contamination was detected by the Kesselring Naval Nuclear Laboratory in Milton.

### Elevated Rates of Birth Defects 10 miles from Natural Gas Wells

The chemicals found in the air around natural gas wells are generally the same chemicals found in compressor station emissions. McKenzie et al. found elevations in rates of birth defects of the cardiovascular system, and border-line elevations in rates of neurotube birth defects among people who live within ten miles of natural gas wells. This is a striking finding, as the study was of 124,842 births between 1996 and 2009, and the fact that birth defects are relatively rare and that more than half of the birth were the controls that did not live within ten miles of gas wells. There was also a significant association with the numbers of well and the distance. The author conclude that the result suggests a positive association between density and proximity to gas wells within a ten-mile radius and birth defects of the heart and possibly neurotube defects, but not with oral clefts, preterm birth or reduced fetal growth.

### Small-Scale Spatial Variations

On the other end of the scale, small-scale spatial variations of only a few feet or yards have been shown to significantly effect personal exposure to ambient PAH concentrations. (Lovinsky-Desir et al. 2016)

Table 2.5c.1b.

## 2.5d. Releases by NYS DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions.

Region 9, Western New York, ranked first with 11.6 million pounds (29.1%), closely followed by Region 6, Western Adirondacks/Eastern Lake Ontario (10.7 million pounds or 27%).

Region 4, Capital Region/Northern Catskills, ranked third with 6.7 million pounds (16.8%).

Total Releases

## Total Releases by County

Total Releases: 40 million pounds

This page intentionally blank.

## Chapter 3: Health Effects

This page intentionally blank.

## Introduction

For most diseases discussed in this study, there is evidence of a relationship between specific **chemical exposures** and specific health outcomes.

An increase in certain vector borne infectious and parasitic diseases may result due to a warmer climate created by greenhouse gases, not because of chemical exposure per se. This is best described as an instance of “systemic causation.”

The WHO provides this definition of epidemiology:

Epidemiology is the study of the distribution and determinants of health-related states or events (including disease), and the application of this study to the control of diseases and other health problems. Various methods can be used to carry out epidemiological investigations: surveillance and descriptive studies can be used to study distribution; analytical studies are used to study determinants. (WHO)

The reader should be aware (1) that within science different conceptions of causality are employed, and (2) there is a difference between how science establishes proof of a relationship and that required in legal adjudication.

In mathematics, one can prove a theorem with absolute certainty of 100%.

However, in medicine, epidemiology (a subset of medicine) and biology, one can never absolutely prove “causation.” Therefore, science uses the “weight-of-the-evidence” and requires that multiple tests of association reach statistical significance at the 95% or 99% confidence interval—this is considered proof of associations so strong as to **imply** causation.

Because the subject matter of epidemiology is populations (not individuals), disease frequency (the rate of disease within a population), diseases patterns in time and place, credible scientific evidence is established when it reaches a 95% “Confidence Interval” (not 100% certainty). Epidemiologists describe the relationship between chemical exposure, co-morbidities and disease in terms of associations or probabilities, not in terms of cause and effect. To be more specific, the presence or absence of a property in a given population in terms of its exposure to a contaminant are expressed in epidemiology as an “odds ratio” (OR), “relative risk” or “risk ratio” (RR), or “hazard ratio” (HR).

When adjudicated in court, to prove harm from chemical exposure plaintiffs do not have to establish that the evidence of a relationship between a chemical exposure and a disease reaches 95% confidence (as it does in epidemiology) but rather that it is “more likely than not” that exposure caused the disease.

In these matters, an understanding of the principles of cognitive science are critical, specifically, the difference between “direct causation” and “systemic causation.”

George Lakoff, Richard and Rhoda Goldman Distinguished Professor of Cognitive Science and Linguistics at the University of California at Berkeley, describes the difference concisely:

Systemic causation is familiar. Smoking is a systemic cause of lung cancer. HIV is a systemic cause of AIDS. Working in coal mines is a systemic cause of black lung disease. Driving while drunk is a systemic cause of auto accidents. Sex without contraception is a systemic cause of unwanted pregnancies.

There is a difference between systemic and direct causation. Punching someone in the nose is direct causation. Throwing a rock through a window is direct causation. Picking up a glass of water and taking a drink is direct causation. Slicing bread is direct causation. Stealing your wallet is direct causation. Any application of force to something or someone that always produces an

immediate change to that thing or person is direct causation. When causation is direct, the word cause is unproblematic.

Systemic causation, because it is less obvious, is more important to understand. A systemic cause may be one of a number of multiple causes. It may require some special conditions. It may be indirect, working through a network of more direct causes. It may be probabilistic, occurring with a significantly high probability. It may require a feedback mechanism. In general, causation in ecosystems, biological systems, economic systems, and social systems tends not to be direct, but is no less causal. And because it is not direct causation, it requires all the greater attention if it is to be understood and its negative effects controlled.

Above all, it requires a name: systemic causation. (Lakoff 2017)

The only quibble we have is that Lakoff seems to suggest most people regard smoking as a systemic cause of lung cancer. We believe that if you asked most people, they would say “smoking causes lung cancer,” the direct implication being it is a “direct cause.” The term “systemic causation” is not in the vocabulary of the average person, and in our experience, it is rare to meet an epidemiologist who possess any familiarity with the concept per se (though their work generally assumes and sometimes expresses the idea). Equally important, most people don’t understand that epidemiology is not the study of individuals but of populations.

In this study we document the presence of 70 chemicals as airborne contaminants released by stationary combustion at natural gas compressor stations as reported by NEI, two additional stack released reported by GHGI (carbon dioxide and methane) not reported by NEI, and three chemicals from fugitive sources reported by GHGI (carbon dioxide, methane and nitrous oxide). In all, there is documented data for 73 chemicals.

In understanding how and under what circumstances these chemicals individually or collectively may adversely affect human health, the terms reviewed above should all be considered.

We have two concerns: (a) the direct and systemic effects of chemicals on human health and (b) the systemic health effects caused by greenhouse gases.

Acute chemical exposures may produce immediate and obvious health effects. Exposures to high levels of carbon monoxide is toxic to all hemoglobin animals, including human. In ordinary parlance we would say that when carbon monoxide poisoning occurs the acute chemical exposure was the direct (and immediate) cause of death.

High levels of air pollution result in asthmatic attacks, but they are not the cause of the patient’s underlying asthma. Because not everyone suffering from asthma has an asthmatic attack on days with particularly bad air pollution, the outcome is probabilistic, which is why an epidemiologist familiar with cognitive science would describe this as systemic causation.

Table 3a provides selected health effects for 6 compressor station pollutants indicating (a) the concern (chemical exposure or climate change) and (b) causation (direct or systemic).

Table 3b provide a list of all 70 stack pollutants and the major categories of disease they are positively associated with.

Table 3a.

## NYS Natural Gas Compressor Stations

Stack Rank	Chemical	Concern	Ch.	Title	Code	Disease description	Causation	Reference
1	Nitrogen oxides  Stack releases: 18,082,570 lbs.	Climate change	1.	Certain infectious and parasitic diseases		E.g., tick borne diseases	Systemic cause	Systemic cause of disease resulting from a warmer climate and spread of infectious and parasitic diseases
		Chemical exposure	2.	Neoplasms	C30-C39	Malignant neoplasms, respiratory system and intrathoracic organs	Systemic cause	Chen et al. 2014, Hamra et al. 2015, Han et al. 2016
		Chemical exposure	2.	Neoplasms	C54	breast (carcinomas)	Systemic cause	Chen et al. 2012, Jørgensen et al. 2016
		Chemical exposure	4.	Endocrine diseases	E11	diabetes mellitus	Systemic cause	Coogan et al. 2012, Eze et al. 2014
		Chemical exposure	10.	Diseases of the respiratory system	J45	asthma	Systemic cause	Di Giampaolo et al. 2011, van der Vliet 2011
2	Carbon monoxide  Stack releases: 12,359,731 lbs.	Chemical exposure	3.	Diseases of the blood, blood-forming organs, immune mechanism		Autoimmune disease	Systemic cause	Science Daily 6 September 2004, Nicholls 2001
		Chemical exposure	6.	Diseases of the nervous system	G30-G32	Other degenerative diseases of the nervous system	Systemic cause	Nicholls 2001
		Chemical exposure	9.	Diseases of the circulatory system	I20-I25	Ischemic heart diseases	Systemic cause	Alfted et al. 1989, Alfted et al. 1989, Nuvolone et al. 2011.
		Chemical exposure	10.	Respiratory system	J40-J47	Chronic lower respiratory diseases	Systemic cause	Sbihi et al. 2016, Tian et al. 2014
		Chemical exposure	20.	Poisoning and certain other consequences of external causes	T58	Toxic effect of carbon monoxide	Direct cause	NIOSH REL: TWA 35 ppm (40 mg/m <sup>3</sup> ) C 200 ppm (229 mg/m <sup>3</sup> ). Acute levels will without exception will sicken all exposed populations and at certain levels kill all people, so CO poisoning can be described as a direct cause poisoning and death. Approximately 40,000 people are treated for CO poisoning annually in the U.S. Signs and symptoms of high inhalation exposure include: headache, tachypnea, nausea, lassitude (weakness, exhaustion), dizziness, confusion, hallucinations; cyanosis; depressed S-T segment of electrocardiogram, angina, syncope (NIOSH Pocket Guide)
3	Volatile organic chemicals  Stack releases: 4,920,396 lbs.	Chemical exposure	4.	Endocrine, nutritional and metabolic diseases		endocrine system effects	Systemic cause	TEDX
		Chemical exposure	5.	Mental and behavioral disorders		coordination (loss) reduced cognitive capacity	Systemic cause	U.S. NIH ToxTown U.S. EPA, U.S. NIH
		Chemical exposure	6.	Nervous system diseases		CNS damage	Systemic cause	U.S. EPA, U.S. NIH
		Chemical exposure	9.	Circulatory system		cardiovascular disease	Systemic cause	Lin et al. 2013, Ye et al. 2017
4	Formaldehyde  Stack releases: 1,309,336 lbs.	Chemical exposure	2.	Neoplasms		Malignant neoplasms	Systemic cause	Known human carcinogen (IARC, State of California)
		Chemical exposure	2.	Neoplasms	C00	Malignant neoplasms, lip	Systemic cause	Meshkov 2014
		Chemical exposure	2.	Neoplasms	C06	Malignant neoplasms, mouth	Systemic cause	Meshkov 2014
		Chemical exposure	2.	Neoplasms	C06	Malignant neoplasms, oral cavity	Systemic cause	Merletti et al., 1991
		Chemical exposure	2.	Neoplasms	C11	Malignant neoplasms, nasopharyngeal	Systemic cause	Coggon et al. 2014, Hauptmann et al. 2004, IARC, Marsh et al. 2002, Puñal-Riobóo et al. 2010, Roush et al. 1987, U.S. NTP ROC 13th
		Chemical exposure	2.	Neoplasms	C15	Malignant neoplasms, esophagus	Systemic cause	Coggon et al. 2014
		Chemical exposure	2.	Neoplasms	C16	Malignant neoplasms, stomach	Systemic cause	Coggon et al. 2014
		Chemical exposure	2.	Neoplasms	C22	Malignant neoplasms, liver	Systemic cause	Coggon et al. 2014
		Chemical exposure	20	Symptoms and signs		Varied	Direct cause	NIOSH REL: Ca TWA 0.016 ppm C 0.1 ppm [15-minute]

Stack Rank	Chemical	Concern	Ch.	Title	Code	Disease description	Causation	Reference
								High exposure levels will typically result in: irritation eyes, nose, throat, respiratory system; lacrimation (discharge of tears); cough; wheezing (NIOSH Pocket Guide)
NA	Carbon dioxide	Climate change	1.	Certain infectious and parasitic diseases		E.g., tick borne diseases	Systemic cause	Systemic cause of disease resulting from a warmer climate and spread of infectious and parasitic diseases
	Stack releases: Amount TBD	Chemical exposure	10.	Diseases of the respiratory system			Systemic cause	Wong et al. 2011
	Fugitive releases: Amount TBD	Chemical exposure	20	Symptoms and signs		Varied	Direct cause	NIOSH REL: TWA 5000 ppm (9000 mg/m <sup>3</sup> ) ST 30,000 ppm (54,000 mg/m <sup>3</sup> ). At high exposure levels inhalation symptoms include: headache, dizziness, restlessness, paresthesia; dyspnea (breathing difficulty); sweating, malaise (vague feeling of discomfort); increased heart rate, cardiac output, blood pressure; coma; asphyxia; convulsions. (NIOSH Pocket Guide)
NA	Methane	Climate change	1.	Certain infectious and parasitic diseases		E.g., tick borne diseases	Systemic cause	Systemic cause of disease resulting from a warmer climate and spread of infectious and parasitic diseases
	Fugitive releases: Amount TBD	Chemical exposure	10.	Respiratory system	J80	acute respiratory distress syndrome (ARDS)	Direct cause	acute respiratory distress syndrome (ARDS)
NA	Nitrous oxides	Climate change	1.	Certain infectious and parasitic diseases		E.g., tick borne diseases	Systemic cause	Systemic cause of disease resulting from a warmer climate and spread of infectious and parasitic diseases
	Fugitive releases: amount TBD	Chemical exposure	15	Pregnancy, childbirth and the puerperium		Miscarriage or fetal death	Systemic cause	ILO 1996
		Chemical exposure	17.	Congenital malformations and deformations		Birth defects, mutations, fetal damage	Systemic cause	ILO 1996
		Chemical exposure	20.	Poisoning and certain other consequences of external causes	T58	Toxic effect of carbon nitrogen oxides	Direct cause	NIOSH REL: TWA 25 ppm (46 mg/m <sup>3</sup> ) (TWA over the time exposed) [*Note: REL for exposure to waste anesthetic gas.] At high exposure levels inhalation symptoms include: dyspnea (breathing difficulty); drowsiness, headache; asphyxia (NIOSH Pocket Guide)

Table 3b.

## Chemicals and Health Effects Ranked by Total Pounds

NYS Natural Gas Compressor Stations, Reported NEI Emissions: 2008 to 2014

				Neoplasms	Blood & immune system	Endocrine & related	Mental & Behavioral	Nervous system	Eye and adnexa	Ear and mastoid process	Circulatory	Respiratory	Digestive	Skin and subcutaneous	Musculoskeletal	Genitourinary	Genitourinary: Urinary	Genitourinary: Pelvis, genitals and breasts	Pregnancy, childbirth and the puerperium	Perinatal period	Congenital malformations & chrom. abnormalities	Symptoms, signs, abnormal clinical & lab. findings	Injury, poisoning	external causes

### 3.1 Certain infectious and parasitic diseases (A00-B99)

As indicated above, for certain infectious and parasitic diseases (Chapter 1 of ICD-10), adverse health effects are not the result of chemical exposures per se, but the result of a warmer climate created by greenhouse gases which lead to their spread and in many cases increased virulence.

The spread of a wide range of both human and animal infectious disease as a result of climate change is unavoidable, and some effects are already clear (Bouzid et al. 2014, Caminade et al. 2014, Confalonieri et al. 2015, Gislason 2014, Heffernan 2013, Medlock and Leach 2014, Parham et al. 2014, Ogden et al. 2014, Rodríguez-Morales 2013, Shuman 2011).

A wide variety of non-infectious and non-parasitic diseases will also increase in incidence as a result of climate change including: allergic disease (Barne et al. 2013, Behrendt and Ring 2012, Bielory et al. 2012), cardiopulmonary disorders (De Blois et al. 2015, Rice et al. 2014), respiratory disease (Barne et al. 2013, Gerardi and Kellerman 2014, Lin et al. 2012, Takaro et al. 2013), and skin diseases (Andersen 2011, Andersen et al. 2012, Balato et al. 2013).

Everyone will be affected by the impact of climate change on health--more vulnerable populations include the elderly (Gamble et al. 2013), children (Bernstein et al. 2011), and manual workers (Applebaum et al. 2016).

This page intentionally blank.

## 3.2. Neoplasms (C00-D48)

### 3.2.1. Carcinogens by Evidence of Carcinogenicity

Fifty-nine of the 70 chemicals released by NYS natural gas compressor stations are associated with neoplastic diseases.

All 18 stations had carcinogenic releases. These totaled an estimated 9.5 million pounds from 2008 to 2014--an annual average of 1.4 million pounds.

Chemicals associated with cancer represented 23.7% of all compressor station releases.

Of the 59 chemicals linked to cancer, 22 chemicals are categorized as “known” human carcinogens by one or more authoritative sources:

1. International Agency for Research on Cancer (IARC) -- the specialized cancer agency of the World Health Organization (WHO),
2. U.S. National Toxicology Program (NTP) -- National Institute of Environmental Health Sciences, National Institutes of Health,
3. U.S. Environmental Protection Agency (EPA),
4. U.S. National Institute for Occupational Safety and Health (NIOSH),
5. U.S. Occupational Safety and Health Administration (OSHA), and
6. State of California, Office of Environmental Health Hazard Assessment (CA/OEHHA) -- part of the California Environmental Protection Agency (Cal/EPA).

Known human carcinogens account for 83% of total carcinogens.

Table 3.2.1a.

## Carcinogens by Evidence of Carcinogenicity

NYS Natural Gas Compressor Station NEI Emissions, 2008 to 2011

Evidence of Carcinogenicity		Location				7 Years (estimate)		
		Ch	Fac	Cn	DEC	Average Annual Pounds	Total Pounds	%
1	Authority: known human carcinogen	23	18	14	6	1,129,164	7,904,153	82.87

[illegible]

### 3.2a. Releases by Chemical

Volatile organic compounds (VOCs) as a group were responsible for 51.6% of all statewide carcinogenic releases, slightly more than 4.9 million pounds. In addition to VOCs as a group, NEI also identifies specific VOCs. Individual VOCs have different levels of evidence of human carcinogenicity. Formaldehyde, which ranks 2<sup>nd</sup>, is classified by IARC as a known human carcinogen. Acetaldehyde, which ranks 7<sup>th</sup>, is classified as a possible human carcinogen by IARC. Methanol, which ranks 10<sup>th</sup>, is classified by EU as having limited evidence of human carcinogenicity (R40). There is both animal and human evidence for the carcinogenicity of acrolein, but it has not been classified by IARC because of the limited amount of evidence available. Benzene, which ranks 9<sup>th</sup>, is universally considered a known human carcinogen (IARC, NTP, EPA, OSHA, NIOSH, CA/OEHHA). VOCs as a group undoubtedly contain a mixture of individuals VOCs, some of which are classified as known, probable or possible human carcinogens, as well as some that have not been classified by an authoritative agency for various reasons including the lack of available evidence upon which to make an assessment. While not every VOC is a carcinogen, many are. The emission reporting category VOCs is, in our opinion, reflective of known human carcinogenic activity and we have included it as a known human carcinogen in this report. Formaldehyde ranked second with 1,309,335 pounds (13.7%), followed by PM10 with 1,259,744 pounds (13.2%). These three chemicals were responsible for 78.5% of all carcinogens released by the state's natural gas compressor stations. The top 10 chemicals accounted for 99.4% of all carcinogenic releases.

Table 3.2a.

#### Neoplastic Diseases by Chemical (Top 20 Carcinogens)

NYS Natural Gas Compressor Station NEI Emissions, 2008 to 2011

Chemical		Location			3 Years	7 Year Estimate: 2008 to 2014		
Rank	Name	Fac's	Cn's	Reg's	Pounds	Average	Pounds	%
1	Volatile organic compounds	18	14	6	2,108,741	702,913	4,920,395	51.59
2	Formaldehyde	18	14	6	561,143	187,047	1,309,335	13.73

### 3.2b. Releases by ICD Category

Neoplasms are subdivided into 3 major groups: malignant neoplasms (C00-C97), in situ neoplasms (D00-D09), benign neoplasms (D10-D36), and neoplasms of uncertain or unknown behavior (D37-D48). Chemicals released by natural gas compressor stations in NYS are positively associated with all four. It should be remembered, that a single chemical can be associated with more than one category of disease.

#### Malignant neoplasms (C00-C97)

Malignant neoplasms are sub-divided into 14 groups--the primary consideration for categorization being the effected organ or organ system. Fifty-six chemicals released by NYS compressor stations (2008-2014) are associated with malignant neoplasms.

All 18 NYS compressor stations had reported releases of chemicals associated with malignant neoplasms.

Four of the top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 1.7 million pounds or 18% of the total, followed by the company compressor in Carlisle (1.4 million pounds or 14.2%) and by its LaFayette facility (1.14 million pounds or 11.9%). These three sites were responsible for 4.2 million pounds or 44% of all statewide releases. The top 5 sites were responsible for 5.9 million pounds or slightly less than two-thirds (62.1%) of the state total. The facility average was 532,453 pounds. (Table 2c)

#### 1. Lip, oral cavity and pharynx (C10-C14)

Fourteen chemicals released by NYS natural gas compressor stations are associated with malignant neoplasms of the lip, oral cavity and pharynx. Specific organs affected include: lips (C00), tongue (C02), buccal, mouth, and oral cavity (C06), salivary gland (C08), nasopharynx (C11), hypopharyngeal (C13), and oral cavity and pharynx (C14).

Four of the top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 226,703 pounds or 15.7% of the total, followed by the company's compressor in LaFayette (186,512 pounds or 13%) and its Carlisle facility (159,281 pounds or 11.1%). These three sites were responsible for 572,496 pounds or 40% of all statewide releases. The top 5 sites were responsible for 852,720 pounds or more than one-half (59.2%) of the state total. The facility average was 80,029 pounds. (Table 2c.1)

#### 2. Digestive organs (C15-C26)

Thirty-eight chemicals released by NYS natural gas compressor stations are associated with digestive system malignancies. Specific organs affected include: esophagus (C15), stomach (C16), duodenum, small intestine (C17), colon (C18), rectum (C20), anus (C21), liver (C22), biliary tract (C24), pancreas (C25), and spleen (C26).

Four of the top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 187,951 pounds or 15.6% of the total, followed by the company's station in LaFayette (187,951 pounds or 12.9%) and its Carlisle facility (160,478 pounds or 11%). These three sites were responsible for 576,136 pounds or 39.4% of all statewide releases. The top 5 sites were responsible for 861,765 pounds or more than one-half (58.9%) of the state total. The facility average was 81,250 pounds. (Table 2c.2)

### 3. Respiratory system and intrathoracic organs (C30-C39)

Thirty-eight chemicals released by NYS natural gas compressor stations are associated with respiratory system and intrathoracic organ malignancies. Specific organs affected include: nasal cavity, nasal mucosa and paranasal sinus (C30), larynx, throat and trachea (C32), bronchus and lung (C34), cardiac and heart (C38), and respiratory tract (C39).

Four of the top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 1.7 million pounds or 18.1% of the total, followed by the company's station in Carlisle (1.3 million pounds or 14.2%) and its LaFayette facility (1.1 million pounds or 11.9%). These three sites were responsible for 4.1 million pounds or 44.2% of all statewide releases. The top 5 sites were responsible for 5.8 million pounds or slightly less than two-thirds (62.1%) of the state total. The facility average was 520,308 pounds. (Table 2c.3)

### 4. Bone and articular cartilage (C40-C41)

Thirty-five chemicals released by NYS natural gas compressor stations are associated with bone and articular cartilage malignancies, specifically, bone carcinoma and osteosarcoma subcutaneous tissue fibrosarcoma (C41).

Four of the top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 1.6 million pounds or 18.4% of the total, followed by the company's station in Carlisle (1.2 million pounds or 14.1%) and its LaFayette facility (1 million pounds or 12%). These three sites were responsible for 3.9 million pounds or 44.5% of all statewide releases. The top 5 sites were responsible for 5.4 million pounds or slightly less than two-thirds (62.1%) of the state total. The facility average was 487,068 pounds. (Table 2c.4)

### 5. Skin (C43-C44)

Fourteen chemicals released by NYS natural gas compressor stations are associated with skin carcinomas (C44).

TGPC's Compressor Station 229 in Eden ranked first with 13,750 pounds or slightly more than half (51.5%) of the total, followed by AG Stony Point compressor (4,553 pounds or 17.1%) and DTI's Woodhull Station (2,883 pounds or 10.8%). These three sites were responsible for 21,187 pounds or more than three-fourths (79.4%) of all statewide releases. The top 5 sites were responsible for 24,199 pounds or 90.1% the state total. The facility average was 1,483 pounds. (Table 2c.5)

### 6. Connective and soft tissue (C45-C49)

Seventeen chemicals released by NYS natural gas compressor stations are associated with connective and soft tissue malignancies, specifically, peritoneal cavity carcinoma and peritoneum mesothelioma (C48), and blood vessel angiosarcoma, carcinoma and hemangiosarcoma, connective tissue carcinoma and sarcoma, heart hemangiosarcoma, liver hemangiosarcoma, and muscle carcinoma (C49).

AG Stony Point Compressor Station ranked first with 7.516 pounds or 27.5% the total, followed by TGPC's compressor in Eden (6,843 pounds or 25%) and AG's Southeast Station (4,304 pounds or 16%). These three sites were responsible for 18,663 pounds or slightly more than two-thirds (68.3%) of all statewide releases. The top 5 sites were responsible for 22,680 pounds or 83% the state total. The facility average was 1,519 pounds. (Table 2c.6)

## 7. Breast and female genital organs (C50-C58)

Twenty-five chemicals released by NYS natural gas compressor stations are associated with breast and female genital organ malignancies. Specific organs affected include: breast adenocarcinoma, carcinoma and carcinosarcoma (C50), cervical carcinoma (C53), carcinoma of the uterus (C55), and ovarian carcinoma and granulosa cell carcinoma (C56).

The top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 766,684 pounds or 17.7% of the total, followed by the company's station in Carlisle (648,570 pounds or 15%) and its Eden facility (529,510 pounds or 12.2%). These three sites were responsible for 1.9 million pounds or 45% of all statewide releases. The top 5 sites were responsible for 2.8 million pounds or slightly less than two-thirds (63.5) of the state total. The facility average was 240,897 pounds. (Table 2c.7)

## 8. Male genital organs (C60-C63)

Thirteen chemicals released by NYS natural gas compressor stations are associated with male genital organ malignancies, specifically, prostate carcinomas (C61) and testes carcinomas (C62).

Four of the top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 222,045 pounds or 15.9% of the total, followed by NFGSC's station in Concord (188,88 pounds or 13.5%) and TGPC's LaFayette facility (179,381 pounds or 12.6%). These three sites were responsible for 590,314 pounds or 42.2% of all statewide releases. The top 5 sites were responsible for 866,213 pounds or slightly less than two-thirds (61.9%) of the state total. The facility average was 77,773 pounds. (Table 2c.8)

## 9. Urinary organs (C64-C68)

Twenty-five chemicals released by NYS natural gas compressor stations are associated with urinary tract malignancies, specifically, kidney carcinoma, cortical adenocarcinoma, renal cell carcinoma (C64), urinary bladder carcinoma and transitional cell carcinoma (C67), and urogenital carcinomas (C68).

The top 4 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 222,047 pounds or 15.8% of the total, followed by the company's station in LaFayette (186,990 pounds or 13%) and its Carlisle facility (159,689 pounds or 11.1%). These three sites were responsible for 575,865 pounds or 39% of all statewide releases. The top 5 sites were responsible for 862,150 pounds or 59% of the state total. The facility average was 80,063 pounds. (Table 2c.9)

## 10. Malignant neoplasms: Eye, brain and central nervous system (C69-C72)

Twenty chemicals released by NYS natural gas compressor stations are associated with eye, brain and central nervous system malignancies, specifically, retinoblastoma and uveal melanoma (C69), brain malignant astrocytoma, carcinoma and glioma (C71), and central nervous system carcinomas (C72).

The top 4 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 222,607 pounds or 15.6% of the total, followed by the company's station in LaFayette (187,876 pounds or 12.9%) and its Carlisle facility (160,382 pounds or 11%). These three sites were

responsible for 575,865 pounds or 39.4 %of all statewide releases. The top 5 sites were responsible for 862,150 or 59% of the state total. The facility average was 81,202 pounds. (Table 2c.10)

#### 11. Malignant neoplasms: Endocrine glands and related structures (C73-C75)

Ten chemicals released by NYS natural gas compressor stations are associated with endocrine glands and related structure malignancies, specifically, thyroid gland C-cell carcinoma, carcinomas and follicular cell carcinoma (C73) and adrenal gland malignant pheochromocytoma and carcinoma (C74), and pituitary gland carcinoma (C75).

Five of the top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company. TGPC's Compressor Station 245 in Winfield ranked first with 222,166 pounds or 18.2% of the total, followed by NPGSC's Concord station (189,058 pounds or 14.7%) and TGPC's LaFayette facility (179,540 pounds or 12.6%). These three sites were responsible for 590,765 pounds, or 42% of all statewide releases. The top 5 sites were responsible for 877,093 or slightly less than two-thirds (62.2%) of the state total. The facility average was 78,393 pounds. (Table 2c.11)

#### 12. Malignant neoplasms: Secondary and ill-defined (C76-C80)

Six chemicals released by NYS natural gas compressor stations are associated with secondary and ill-defined malignancies, specifically, head carcinoma (C76).

Algonquin Gas Transmission Company's facility in Stony Point, Rockland County, ranked first with 10,793 pounds or slightly less than one-third (32.4%) of the total, followed by the company's facility located in the village of Brewster in the town of Southeast (6,858 pounds or 20.6%). TCPC's station in Eden, Eire County, ranked third (5,172 pounds or 15.5%). These three sites were responsible for 22,823 or slightly more than two-thirds (68.5%) of the total. The top 5 sites were responsible for 28,724 or 86.2% of the state total. The facility average was 1,851 pounds. (Table 2c.12)

#### 13. Malignant Neoplasms, Stated or Presumed to be Primary, of Lymphoid, Haematopoietic and Related Tissue (C81-C96)

Thirty-one chemicals released by NYS natural gas compressor stations are associated with malignant neoplasms stated or presumed to be primary, of lymphoid, haematopoietic and related tissue. These diseases include: Hodgkin's disease (C81), other and unspecified types of non-Hodgkin's lymphoma, including histiocytic sarcomas, lymph sarcomas, lymph system carcinomas and reticulum cell sarcomas (C85), multiple myeloma and malignant plasma cell neoplasms (C90), lymphoid leukemia (C91), myeloid leukemia (C92), leukemia of unspecified cell type, including childhood leukemia (C95), and other and unspecified malignant neoplasms of lymphoid, haematopoietic and related tissue, including blood carcinoma, unspecified leukemia, hematologic and hematopoietic carcinoma (C96).

Table 3.b.

### 3.2d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York's 9 DEC regions. All 6 regions had releases of carcinogens.

DEC Region 9, Western New York, ranked first with 2.5 million pounds or 26% of the state total, followed by Region 6, Western Adirondacks/Eastern Lake Ontario (1,810,984 pounds or 19%) and Region 4, Capital Region/Northern Catskills (1,765,328 pounds or 18.5%). These three regions are responsible for slightly more than one-half (53%) of all toxic releases.

### 3.2e. Releases by County

Herkimer County ranked first with 1.8 million pounds or 19% of the state total, followed by Erie County (1,360,816 pounds or 14.27%) and Schoharie with a slightly smaller total (1,360,333 pounds or 14.26%). These three counties are responsible for nearly one-half (47.5%) of all carcinogenic releases.

The top five counties were responsible for slightly more than two-thirds (67.6%) of the state total.

The 14-county average was 681,304 pounds.

Table 3.2e.

### 3.3. Diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism (D50-D89)

#### 3.3a. Releases by Chemical

Forty-one of the 70 chemicals released by NYS natural gas compressor stations are associated with diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism (ICD 10, Chapter 3). All 18 stations reported such releases. These totaled an estimated 18.7 million pounds from 2008 to 2014--an annual average of 2.7 million pounds.

Chemicals associated with blood and immune system diseases represented 47% of all reported natural gas compressor station releases.

Carbon monoxide was responsible for almost two-thirds (65.9%) of all statewide chemical releases. Volatile organic compounds as a group rank second with 4.9 million pounds (26.2%), followed by formaldehyde with 1.3 million pounds (7%). These three chemicals accounted for 99.1% of the state total.

### 3.3b. Releases by ICD Category

Diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism into 5 major groups. Chemicals released by natural gas compressor stations are positively associated with two of them. It should be remembered, that a single chemical can be associated with more than one category of disease.

**D70-D77:** Twenty-seven chemicals are associated with Coagulation defects, purpura and other hemorrhagic conditions These chemicals were released by all 18 stations.

**D80-D89:** Eighteen chemicals had effects broadly characterized as Other diseases of blood and blood-forming organs

### 3.3c. Releases by Facility

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

TGPC's Compressor Station 245 in Winfield ranked first with 4.1 million pounds or slightly more than one-fifth of the total, followed by the Compressor 249 in Carlisle (2.1 million pounds or 11.1%) and by its LaFayette facility (2 million pounds or 10.3). These three sites were responsible for 8.1 million pounds or 43% of all statewide releases of chemicals associated with blood and immune system disorders.

The top 5 sites were responsible for 11 million pounds (58.5%) of the state total.

The facility average was 1,048,773 pounds.

### 3.3d Releases by DEC Region

Six of New York State's nine DEC regions reported releases of toxic chemicals associated with blood and immune system disorders.

DEC Region 9, Western New York, ranked first with an estimated 5.7 million pounds (30.2%) of releases from 2008 to 2014. Region 6, Western Adirondacks/Eastern Lake Ontario, second with 4.2 million pounds (22.5%), followed by Region 4, Capital Region/Northern Catskills with 3.2 million pounds (17.2%).

### 3.3e. Releases by County

Herkimer County ranked first with 4.2 million pounds or 22.5% of the state total, followed by Erie County (2.5 million pounds or 13.3%) and Schoharie County (2.1 million pounds or 11.2%). These three counties are responsible for nearly one-half (48%) of all releases associated with blood and immune system diseases.

The top five counties were responsible for 12.8 million pounds or slightly more than two-thirds (68.2%) of the state total.

The 14-county average was 1,339,381 pounds.

## 3.4. Endocrine, Nutritional and Metabolic Diseases (E00-E90)

### 3.4a. Releases by Chemical

Fifty-one of the 70 chemicals released by NYS natural gas compressor stations are associated with endocrine, nutritional and metabolic disorders (ICD 10, Chapter 4).

All 18 stations reported such releases. These totaled an estimated 7.1 million pounds from 2008 to 2014--an annual average of slightly more than 1 million pounds a year.

Chemicals associated with these effects accounted for 17.8% of all reported natural gas compressor station releases.

VOCs were responsible for 4.9 million pounds or slightly more than two-thirds (68.1%) of all statewide releases. Formaldehyde ranked second (1.3 million pounds or 18.4%), followed by PM Condensable (540,267 pounds or 7.6%). These three chemicals accounted for 95.1% of all releases.

The top 5 chemicals were responsible for 98.7% of the state total.

Table 3.4a.

### 3.4b. Releases by ICD Category

**E00-E35:** Forty-seven chemicals are associated with endocrine diseases. These include: adrenal weight change, androgen effects, delayed puberty, thymus weight changes, and thyroid hypofunction and other thyroid disorders.

**E70-E90:** Seventeen chemicals are associated with metabolic disorders. These include: biochemical and metabolic effects, homeostasis, hyperchloremic acidosis, and serum composition (changes: e.g. TP, bilirubin, cholesterol).

Table 3.04a.

### 3.4c. Releases by Facility

All 18 natural gas compressor stations in NYS reported releasing these chemicals.

Four of the top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

TGPC's Compressor Station 245 in Winfield ranked first with 1.3 million pounds (17.5%), followed by the Compressor Station 249 in Carlisle (948,972 pounds or 13.4%) and Compressor 241 in LaFayette (874,287 pounds or 12.2%). These three sites were responsible for 43% of all statewide releases.

The top 5 facilities were responsible for 61% of the total.

The facility average was 397,734 pounds.

## E00-E99 Chemicals as % of Each Compressor Station's Total Releases

### 3.4d. Releases by DEC Region

Six of New York State's nine DEC regions reported releases of chemicals associated with endocrine and metabolic diseases.

DEC Region 9, Western New York, ranked first with 1.8 million pounds (26%) from 2008 to 2014. Region 6, Western Adirondacks/Eastern Lake Ontario, ranked second with 1.3 million pounds (18.7%), closely followed by Region 3, Lower Hudson Valley, with 1.2 million pounds (17.5%).

### 3.4e. Releases by County

All fourteen counties where compressor stations are located reported releases of chemicals linked to endocrine and metabolic disorders.

Herkimer County ranked first with 1.3 million pounds or 18.7% of the state total, followed by Schoharie County (958,972 pounds or 13.5%) and Erie County (911,425 pounds or 12.8%). These three counties are responsible for nearly one-half (45%) of all releases.

The top five counties were responsible for 12.8 million pounds or slightly less than two-thirds (66.2%) of the state total.

The 14-county average was 508,382 pounds.

## 3.5. Mental and Behavioral Disorders (F00-F99)

### 3.5a. Releases by Chemical

***Thirty-four of the 70 chemicals released by NYS natural gas compressor reported to NEI are associated with mental and behavioral disorders (ICD-10, Chapter 5).***

***All 18 stations reported such releases. These totaled an estimated 18.7 million pounds from 2008 to 2014--an annual average of 2.7 million pounds.***

Chemicals associated with mental and behavioral disorders represented 47% of all reported toxic releases reported from natural gas compressor stations reported to NEI.

Carbon monoxide was responsible for almost two-thirds (65.9%) of statewide releases of mental and behavioral system toxicants. Volatile organic compounds as a group ranked second (4.9 million pounds or 26.3%), followed by formaldehyde (1.3 million pounds or 7%). These three chemicals accounted for 99.96% of the state total.

### 3.5b. Releases by ICD Category

Mental and behavioral disorders are divided into 11 major groups.

Chemicals released by natural gas compressor stations are positively associated with 8 of them. It should be remembered that a single chemical can be associated with more than one disease group.

**F00-F09:** Ten chemicals are associated with organic, including symptomatic, mental disorders. Specific effects associated with these eight chemicals include euphoria, hallucinations, mood disturbance, and personality changes. These chemicals were released by all 18 facilities.

**F20-F29:** Two chemicals, carbon monoxide and mercury, are associated with schizophrenia, schizotypal and delusional disorders, including delusions and psychosis (manic depressive). These chemicals were released by all 18 facilities.

**F30-F39:** Thirteen chemicals are associated with mood (affective) disorders. Excitement and depression are the two specific effects found in the peer-reviewed literature. These chemicals were released by all 18 facilities.

**F40-F48:** Twelve chemicals are associated with neurotic, stress-related and somatoform disorders, including anxiety, incoordination, panic attacks and stupor. These chemicals were released by all 18 facilities.

**F50-F59:** Nineteen chemicals are connected to behavioral syndromes associated with physiological disturbances and physical factors, specifically, aimless wandering behavior, anorexia (loss of appetite), mental alertness and unspecified behavioral effects. These chemicals were released by all 18 facilities.

**F60-F69:** Two chemicals are associated with disorders of adult personality and behavior, specifically, aggression. Releases were reported by all 18 compressor stations.

**F80-F89:** Seven chemicals are connected to disorders of adult personality and behavior, including learning ability, decrease in manual dexterity and reduced cognitive capacity. These chemicals were released by all 18 facilities.

**F99:** Seven chemicals are associated with unspecified mental disorders.

### 3.5c. Releases by Facility

All 18 natural gas compressor stations in NYS reported releasing chemicals associated with mental and behavioral disorders,

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

TGPC's Compressor Station 245 in Winfield ranked first with 4.1 million pounds (22%), followed by Compressor Station 249 in Carlisle (2.1 million pounds or 11.1%) and Compressor 241 in LaFayette (2 million pounds or 10.3%). These three sites were responsible for 43% of all statewide releases.

The top 5 facilities were responsible for 58% of the total.

The facility average was 1,048,493 pounds.

### 3.5d. Releases by DEC Regions

The 18 compressor stations analyzed are in 6 of New York's 9 DEC regions. All 6 regions had releases of chemicals associated with mental and behavioral disorders.

DEC Region 9, Western New York, ranked first with 5.7 million pounds or slightly less than one-third of total releases from 2008 to 2014. Region 6, Western Adirondacks/Eastern Lake Ontario, second with 4.2 million pounds (22.5%), followed by Region 4, Capital Region/Northern Catskills, 3.2 million pounds (17.2%).

### 3.5e. Releases by County

All fourteen counties where compressor stations are located reported releases of chemicals linked to mental and behavioral disorders.

Herkimer County ranked first with 4.2 million pounds or 22.5% of the state total, followed by Erie County (2.5 million pounds or 13.3%) and Schoharie County (2 million pounds or 11.2%). These three counties are responsible for nearly one-half (47%) of all releases.

The top five counties were responsible for 12.8 million pounds or slightly more than two-thirds (68.1%) of the state total.

The 14-county average was 1,339,021 pounds.

## 3.6. Diseases of the Nervous System (G00–G99)

### 3.6a. Releases by Chemical

***Forty-two of the 70 chemicals released by NYS natural gas compressor stations are associated with nervous system disorders (ICD-10, Chapter 6). All 18 stations reported such releases. These totaled an estimated 19 million pounds from 2008 to 2014--an annual average of 2.7 million pounds.***

Chemicals associated with nervous system diseases represent 47.6% of all reported toxic releases from NYS natural gas compressor stations reported to NEI.

Carbon monoxide was responsible for almost two-thirds (65.1%) of statewide releases of nervous system toxicants. Volatile organic compounds as a group ranked second (4.9 million pounds or 26%), followed by formaldehyde (1.3 million pounds or 6.9%). These three chemicals accounted for 97.9% of the state total.

Table 3.6a.

### 3.6b. Releases by ICD Category

Diseases of the nervous system are subdivided into 11 major categories.

Chemicals released by natural gas compressor stations are positively associated with 6 of them. It should be remembered that a single chemical can be associated with more than one disease group.

**G00-G09:** Five chemicals are associated with inflammatory diseases of the central nervous system, specifically, amyotrophic lateral sclerosis. These chemicals were released by all 18 stations.

**G20-G26:** Two chemicals are associated with extrapyramidal and movement disorders, specifically, olfactory nerve changes. These chemicals were released by 8 stations.

**G40-G47:** Ten chemicals are associated with episodic and paroxysmal disorders, specifically, altered sleep time (including change in righting reflex), insomnia, peripheral nerve effects, sleep disorders, and sleepiness. These chemicals were released by 17 stations.

**G60-G64:** Two chemicals are associated with polyneuropathies and other disorders of the peripheral nervous system. These chemicals were released by all 18 stations.

**G80-G83:** One chemical, carbon monoxide, is associated with cerebral palsy and other paralytic syndromes. It is released by all stations.

**G90-G99:** Forty-two chemicals are associated with other disorders of the nervous system.

Table 3.6b.

### 3.6c. Releases by Facility

All 18 natural gas compressor stations in NYS reported releasing chemicals associated with nervous system disorders.

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

TGPC's Compressor Station 245 in Winfield ranked first with 4.1 million pounds (22%), followed by Compressor Station 249 in Carlisle (2.1 million pounds or 11.1%) and Compressor 241 in LaFayette (2 million pounds or 10.3%). These three sites were responsible for 43% of all statewide releases.

The top 5 facilities were responsible for 58% of the total.

The facility average was 1,062,124 pounds.

### 3.6d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York's 9 DEC regions. All 6 regions had releases of chemicals associated with mental and nervous system disorders.

DEC Region 9, Western New York, ranked first with 5.7 million pounds or slightly less than one-third (30.2%) of total releases from 2008 to 2014. Region 6, Western Adirondacks/Eastern Lake Ontario, second with 4.3 million pounds (22.4%), followed by Region 4, Capital Region/Northern Catskills, 3.3 million pounds (17.2%).

### 3.6e. Releases by County

All fourteen counties where compressor stations are located reported releases of chemicals linked to nervous system disorders.

Herkimer County ranked first with 4.3 million pounds or 22.4% of the state total, followed by Erie County (2.5 million pounds or 13.3%) and Schoharie County (2.1 million pounds or 11.2%). These three counties are responsible for nearly one-half (48.9%) of all releases.

The top five counties were responsible for 12.8 million pounds or slightly more than two-thirds (68%) of the state total.

The 14-county average was 1,356,535 pounds.

## 3.7. Diseases of the Eye and Adnexa (H00-H59)

### 3.7a. Releases by Chemical

***Forty-one of the 70 chemicals released by NYS natural gas compressor stations are associated with diseases of the eye and adnexa (ICD-10, Chapter 7). All 18 stations reported such releases. These totaled an estimated 24.7 million pounds from 2008 to 2014--an annual average of 3.5 million pounds.***

Chemicals associated with eye and adnexa diseases represent 61.8% of all reported toxic releases from NYS natural gas compressor stations reported to NEI.

Nitrogen oxides were responsible for slightly less than three-fourths (73.2%) of statewide releases of chemicals linked to diseases of the eye and adnexa. Volatile organic compounds as a group ranked second (4.9 million pounds or 20%), followed by formaldehyde (1.3 million pounds or 5.3%). These three chemicals accounted for 98% of the state total.

Table 3.7a.

### 3.7b. Releases by ICD Category

Diseases of the eye and adnexa system are subdivided into 12 major groups. Chemicals released by natural gas compressor stations are positively associated with 8 of them. It should be remembered, that a single chemical can be associated with more than one category of disease.

**H00-H06:** Nine chemicals are associated with disorders of eyelid, lacrimal system and orbit. Specific effects include: lacrimation and ptosis. These chemicals were released by all 18 stations.

**H10-H13:** Ten chemicals are associated with conjunctival disorders. Specific effects include: conjunctivitis and conjunctival irritation. These chemicals were released by all 18 stations.

**H15-H19:** Three chemicals are associated with disorders of sclera and cornea. Specific effects include: cornea damage and clouding. These chemicals were released by 13 stations.

**H20-H22:** A single chemical, propylene oxide, is associated with disorders of iris and ciliary body, specifically, iritis. Eight stations reported releases of this chemical.

**H30-H36:** Three chemicals are associated with glaucoma. Eighteen stations reported its release.

**H40-H42:** Two chemicals are associated with glaucoma. Fourteen stations reported its release.

**H53-H54:** Eleven chemicals are associated with visual disturbances and blindness. Eighteen stations reported their release.

**H55-H99:** Thirty-nine chemicals are associated with other disorders of eye and adnexa.

### 3.7c. Releases by Facility

All 18 natural gas compressor stations in NYS reported releasing chemicals associated with diseases of the eye and adnexa.

The top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company.

TGPC's Compressor Station 245 in Winfield ranked first with 7 million pounds (28.3%), followed by Compressor Station 229 in Eden (3.7 million pounds or 15%) and Compressor 249 in Carlisle (2.6 million pounds or 10.4%). These three sites were responsible for more than one-half (53.7%) of all statewide releases.

The top 5 facilities were responsible for slightly less than two-thirds (65.4%) of the total.

The facility average was 1,379,496 pounds.

### 3.7d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York's 9 DEC regions. All 6 regions had releases of chemicals associated with mental and diseases of the eye and adnexa.

DEC Region 6, Western Adirondacks/Eastern Lake Ontario, ranked first with 7.2 million pounds or 20.3% of total releases from 2008 to 2014. Region 9, Western New York, was a close second with 6.9 million pounds (28.2%), followed by Region 4, Capital Region/Northern Catskills, 3.9 million pounds (16.1%).

### 3.7e. Releases by County

All fourteen counties where compressor stations are located reported releases of chemicals linked to diseases of the eye and adnexa.

Herkimer County ranked first with 7.2 million pounds or 29.1% of the state total, followed by Erie County (4.6 million pounds or 18.7%) and Schoharie County (2.6 million pounds or 10.5%). These three counties are responsible for more than one-half (58.3%) of all releases.

The top five counties were responsible for 17.3 million pounds or slightly more than two-thirds (70%) of the state total.

The 14-county average was 1,765,283 pounds.

## 3.8. Diseases of the Ear and Mastoid Process (H60-H95)

### 3.8a. Releases by Chemical

Fifteen of the 70 chemicals released by NYS natural gas compressor stations are associated with diseases of the ear and mastoid process (ICD-10, Chapter 8). All 18 stations reported such releases. These totaled an estimated 17.3 million pounds from 2008 to 2014—an annual average of 2.5 million pounds.

Chemicals associated with diseases of the ear and mastoid process represented 43.5% of all reported releases by natural gas compressor stations.

Two chemicals, carbon monoxide and volatile organic compounds, were responsible for 99.8% of all statewide releases.

Table 3.8a.

### 3.8b. Releases by ICD Category

Diseases of the ear and mastoid process are subdivided into 4 major groups. Chemicals released by natural gas compressor stations are positively associated with two of them. It should be remembered, that a single chemical can be associated with more than one category of disease.

**H80-H83:** Fifteen chemicals are associated with diseases of inner ear, including, change in cochlear structure or function, hearing deficits and hearing disturbance. These chemicals were released by all 18 stations.

**H90-H95:** These fifteen all had effects broadly characterized as other disorders of ear, characterized as changes in hearing acuity, hearing loss, and ototoxicity.

Table 3.8b.

### 3.8c. Releases by Facility

All 18 natural gas compressor stations in NYS reported releasing chemicals associated with diseases of the ear and mastoid process.

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

TGPC's Compressor Station 245 in Winfield ranked first with 3.8 million pounds (22%), followed by Compressor Station 249 in Carlisle (1.9 million pounds or 11.1%) and Compressor 241 in Lafayette (1.8 million pounds or 10.1%). These three sites were responsible for 43.1% of all statewide releases.

The top 5 facilities were responsible for more than one-half (58.4%) of the total.

The facility average was 970,115 pounds.

### 3.8d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York's 9 DEC regions. All 6 regions had releases of chemicals associated with mental and diseases of the eye and adnexa.

Region 9, Western New York, ranked first with 5.2 million pounds or 29.9% of total releases from 2008 to 2014. DEC Region 6, Western Adirondacks/Eastern Lake Ontario, was second with 4 million pounds (23%), followed by Region 4, Capital Region/Northern Catskills, 3 million pounds (17.5%).

### 3.8e. Releases by County

All fourteen counties where compressor stations are located reported releases of chemicals linked to diseases of the ear and mastoid process.

Herkimer County ranked first with 4 million pounds or 23% of the state total, followed by Erie County (2.2 million pounds or 12.8%) and Schoharie County (2 million pounds or 11.2%). These three counties are responsible for slightly less than one-half (47%) of all releases.

The top five counties were responsible for 11.8 million pounds or slightly more than two-thirds (68%) of the state total.

The 14-county average was 1,238,962 pounds.

## 3.9. Diseases of the Circulatory System (I00-I99)

### 3.9a. Releases by Chemical

Thirty-one of the 70 chemicals released by NYS natural gas compressor stations are associated with diseases of the circulatory system (ICD-10 Chapter 9). All 18 stations reported such releases. These totaled an estimated 16.2 million pounds from 2008 to 2014--an annual average of 2.3 million pounds.

Eighteen of these 31 chemicals are categorized as known human circulatory system toxicants by U.S. ATSDR.

Carbon monoxide ranked first accounting for slightly more than three-fourths (76.5%) of the state total or 12.4 million pounds. Formaldehyde ranked second (1,309,335 pounds or 8.1%), closely followed by PM10 (1,259,744 pounds or 7.8%).

The average annual release was 5.6 million pounds.

Chemicals associated with circulatory system diseases represented 40.4% of releases by the state's natural gas compressor stations.

Table 3.9a.

### 3.9b. Releases by ICD Category

Circulatory system diseases are subdivided into 10 major groups. Chemicals released by natural gas compressor stations in NYS are positively associated with four of them. It should be remembered, that a single chemical can be associated with more than one category of disease.

**I10-I15:** One chemical released by 14 of the 18 compressor stations reporting to NEI has been associated with hypertensive disease.

**I10-I15:** One chemical released by 16 of the 18 compressor stations reporting to NEI has been associated with chronic rheumatic heart diseases.

**I30-I52:** Sixteen chemicals are associated with other forms of heart disease. Specific diseases cite in the literature include: cardiac arrhythmia, heart weight change, increased cardiovascular mortality, and acute pulmonary edema. These chemicals were in the emission inventories of all 18 NYS compressor stations reporting to NEI and totaled 1.6 million pounds.

**I70-I79:** Six chemicals are associated with diseases of arteries, arterioles and capillaries: blood vessels changes and regional, general arteriolar or venous dilation. All 18 stations reported release of these chemicals. Aggregate releases totaled 569,641 pounds.

**I95-I99:** Twenty-two chemicals are associated with other and unspecified disorders of the circulatory system. These totaled 5.3 million pounds.

### 3.9c. Releases by Facility

All 18 natural gas compressor stations in NYS reported releases chemicals associated with circulatory system disease.

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 3.6 million pounds or 22% of the state total, followed by Compressor Station 249 in Carlisle (1.8 million pounds or 11.1%) and Compressor Station 241 in LaFayette (1.6 million pounds or 9.9%). These three facilities were responsible for 43% of the state total.

The top 5 facilities were responsible for 59% of all releases.

The facility average was 902,768 pounds.

### 3.9d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York's 9 DEC regions. All 6 regions had releases of chemicals associated with circulatory diseases.

DEC Region 9, Western New York, ranked first with an estimated 5.1 million pounds of toxic releases from 2008 to 2014. This represented nearly one-third (31.4%) of the state total. Region 6, Western Adirondacks/Eastern Lake Ontario, ranked second (3.7 million pounds or 23%), followed by Region 4, Capital Region/Northern Catskills (2.8 million pounds or 17.6%).

### 3.9e. Releases by County

All 14 counties where compressor station are located reported releases of chemicals linked to circulatory system diseases.

Herkimer County ranked first with 3.7 million pounds or 23% of the state total, followed by Erie County (2.4 million pounds or 14.9%) and Schoharie (1.8 million pounds or 11.2%). These three counties are responsible for nearly one-half (49.1%) of all toxic releases.

The top five counties were responsible for 69%.

The 14-county average was 1,153,577 pounds.

## 3.10. Diseases of the Respiratory System (J00-J99)

### 3.10a. Releases by Chemical

***Fifty-one of the 70 chemicals released by NYS natural gas compressor stations are associated with diseases of the respiratory system (ICD-10 Chapter 10). Releases of respiratory toxicants were reported by all 18 stations and totaled an estimated 39.6 million pounds from 2008 to 2014--an annual average of 5.7 million pounds.***

Chemicals associated with respiratory system diseases represented 98.6% of releases by the state's natural gas compressor stations.

Thirty-five of these 51 chemicals are categorized as known human respiratory toxicants by one or more authoritative sources (U.S. ATSDR, U.S. NIOSH, U.S. OSHA, State of California OEHHA, or the European Union).

Nitrogen oxides ranked first with 18.1 million pounds or 46% of the total, followed by carbon monoxide (12.4 million pounds or 31.3%) and volatile organic compounds (4.9 million pounds or 12.5%). These three chemicals accounted for 35.4 million pounds or 89.7% of all releases.

The top 10 chemicals were responsible for 99.8% of all respiratory toxicants.

Table 3.10a.

### 3.10b. Releases by ICD Category

Respiratory system diseases are subdivided into 10 major groups. Chemicals released by natural gas compressor stations in NYS are positively associated with four of them. It should be remembered, that a single chemical can be associated with more than one category of disease.

**J30-J39:** Eleven chemicals are associated with other diseases of upper respiratory tract, including: epithelial cell hyperplasia of the larynx, mucous membrane irritation, nasal irritation, nasal lesions, nasal septum deviation and ulceration, perforated septum, pharynx irritation, and throat irritation. These were released by 18 facilities.

**J40-J47:** Twenty-three chemicals are associated with lung diseases due to external agents, including asthma and asthma-like allergy, bronchiolar constriction, bronchitis, bronchospasm, emphysema, and changes in pulmonary vascular resistance.

**J68-J70:** Twenty-five chemicals are associated with lung diseases due to external agents, including sensitization by inhalation, breathing difficulty and irregularities, bronchial irritation and pneumonia, chemical pneumonitis, exacerbation of preexisting breathing problems, pneumonia, and shortness of breath. These were released by 18 facilities.

**J80-J84:** Nine chemicals are associated with other respiratory diseases principally affecting the interstitium were released by all 18 facilities.

**J95-J99:** All fifty-one chemicals are associated with other or unspecified diseases of the respiratory system.

### 3.10c. Releases by Facility

All natural gas compressor stations in NYS reported releases chemical associated with respiratory system disease.

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 10.4 million pounds or 26.2% of the state total. Two other compressor station operated by that company ranked second and third: Compressor Station 229 in Eden (5 million pounds or 12.7%) and Compressor Station 249 in Carlisle (4.2 million pounds or 10.7%). These three facilities were responsible for slightly less than one-half (49.6%) of the state total.

The top 5 facilities were responsible for 63% of all releases.

The facility average was 2.2 million pounds.

### 3.10d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with respiratory system diseases.

DEC Region 9, Western New York, ranked first with an estimated 29.2 million pounds (29.2%) of respiratory toxicants releases from 2008 to 2014. Region 6, Western Adirondacks/Eastern Lake Ontario, was a close second with 10.7 million pounds (27.05%).

### 3.10e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals linked to respiratory system diseases.

Herkimer County ranked first with 10.7 million pounds or 27% of the state total, followed by Erie County (6.8 million pounds or 17.1%) and Schoharie County (4.2 million pounds or 10.7%). These three counties are responsible for more than one-half (54.9%) of all toxic releases.

The top five counties were responsible for 69%.

## 3.11. Diseases of the Digestive System (K00-K93)

### 3.11a. Releases by Chemical

Fifty-two of the 70 chemicals released by NYS natural gas compressor stations are associated with digestive diseases (ICD-10 Chapter 11). Releases of digestive system toxicants were reported by all 18 stations and totaled an estimated 38.2 million pounds from 2008 to 2014--an annual average of 5.5 million pounds.

Chemicals associated with digestive system diseases represented 95.7% of releases by the state's natural gas compressor stations.

Nitrogen oxides ranked first with 18.1 million pounds or 47.3% of the total, followed by carbon monoxide (12.4 million pounds or 32.3%) and volatile organic compounds (4.9 million pounds or 12.9%). These three chemicals accounted for 35.4 million pounds or 92.4% of all releases.

The top 10 chemicals were responsible for 99.9% of all digestive toxicants.

The average annual release was 5.5 million pounds.

Table 3.11a.

### 3.11b. Releases by ICD Category

Digestive system diseases are subdivided into 9 major groups. Chemicals released by natural gas compressor stations in NYS are positively associated with 8 of them. It should be remembered, that a single chemical can be associated with more than one category of disease.

**K00-K31:** Seven chemicals are associated with diseases of esophagus, stomach and duodenum, including esophagus (change in structure or function of the esophagus, esophageal inflammation and ulceration, gastritis, and stomach bleeding. All 18 facilities reported releases.

**K35-K38:** Two chemicals are associated with diseases of the appendix.

**K50-K52:** Three chemicals are associated with noninfective enteritis and colitis.

**K55-K63:** Three chemicals are associated with other diseases of intestines, including enteric disease and small intestine (ulceration or bleeding).

**K65-K67:** A single chemical is associated with diseases of peritoneum.

**K70-K77:** Twenty-four chemicals are associated with diseases of the liver, including cirrhosis, hepatitis, and liver damage, fatty degeneration, function impairment, injury, swelling, and weight changes.

**K80-K87:** Three chemicals are associated with disorders of gallbladder, biliary tract and pancreas.

**K90-K93:** Thirty-eight chemicals are associated with other diseases of the digestive system.

### 3.11c. Releases by Facility

All natural gas compressor stations in NYS reported releases chemical associated with diseases of the digestive system.

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 10.2 million pounds or 26.5% of the state total. Two other compressor station operated by that company ranked second and third: Compressor Station 229 in Eden (4.9 million pounds or 12.7%) and Compressor Station 249 in Carlisle (4 million pounds or 10.5%). These three facilities were responsible for slightly less than one-half (49.6%) of the state total.

The top 5 facilities were responsible for 63% of all releases.

The facility average was 2.1 million pounds.

### 3.11d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with respiratory system diseases.

DEC Region 9, Western New York, ranked first with an estimated 11.2 million pounds (29.3%) of digestive toxicants releases from 2008 to 2014. Region 6, Western Adirondacks/Eastern Lake Ontario, was a close second with 10.5 million pounds (27.3%), followed by Region 4, Capital Region/Northern Catskills (6.4 million pounds or 16.5%).

### 3.11e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals linked to digestive system diseases.

Herkimer County ranked first with 10.5 million pounds or 27.3% of the state total, followed by Erie County (6.5 million pounds or 17.1%) and Schoharie County (4 million pounds or 10.5%). These three counties are responsible for more than one-half (54.9%) of all toxic releases.

The top five counties were responsible for 69.4%.

The country average was 2.7 million pounds.

## 3.12. Diseases of the Skin and Subcutaneous Tissue (L00-L99)

### 3.12a. Releases by Chemical

Forty-eight of the 70 chemicals released by NYS natural gas compressor stations are associated with skin and subcutaneous tissue diseases (ICD-10 Chapter 12). Releases of these toxicants were reported by all 18 stations and totaled an estimated 27.6 million pounds from 2008 to 2014--an annual average of 3.9 million pounds.

Chemicals associated with diseases of the skin and subcutaneous tissue represented 69% of releases by the state's natural gas compressor stations.

Nitrogen oxides ranked first with 18.1 million pounds or slightly less than two-thirds (65.6%) of the total, followed by volatile organic compounds (4.9 million pounds or 17.8%) and formaldehyde (1.3 million pounds or 4.8%). These three chemicals accounted for 24.3 million pounds or 88.2 of all releases.

The top 10 chemicals were responsible for 96.6% of all cutaneous and subcutaneous toxicants.

Table 3.12a.

### 3.12b. Releases by ICD Category

Skin and subcutaneous diseases are subdivided into 8 major groups. Chemicals released by natural gas compressor stations in NYS are positively associated with 3 of them. It should be remembered, that a single chemical can be associated with more than one category of disease.

**L20-L30:** Seven chemicals are associated with dermatitis and eczema.

**L50-L54:** Five chemicals are associated with urticaria and erythema.

**L80-L99:** Forty-seven chemicals are associated with other disorders of the skin and subcutaneous tissue.

### 3.12c. Releases by Facility

All natural gas compressor stations in NYS reported releases chemical associated with diseases of the skin and subcutaneous tissue diseases.

The top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 7.6 million pounds or 27.2% of the state total, followed by Compressor Station 229 in Eden (4.1 million pounds or 14.8%) and Compressor Station 249 in Carlisle (3.1 million pounds or 11.1%). These three facilities were responsible for slightly less than one-half (53.1%) of the state total.

The top 5 facilities were responsible for slightly less than two-thirds (65.3%) of all releases.

The facility average was 1.5 million pounds.

Table 3.12c.

### 3.12d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with skin and subcutaneous tissue diseases.

DEC Region 6, Western Adirondacks/Eastern Lake Ontario, ranked first with 7,750,252 pounds (28.1%), closely followed by Region 9, Western New York (7,652,886 pounds or 27.7%). Region 4, Capital Region/Northern Catskills ranked third with 4.6 million pounds (16.6%).

### 3.12e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals linked to cutaneous and subcutaneous diseases.

Herkimer County ranked first with 7.8 million pounds or 28.1% of the state total, followed by Erie County (5.2 million pounds or 18.7%) and Schoharie County (3.1 million pounds or 11.1%). These three counties are responsible for more than one-half (57.8%) of all toxic releases.

The top five counties were responsible for 70%.

The country average was 2 million pounds.

### 3.13. Diseases of the Musculoskeletal System and Connective Tissue (M00-M99)

#### 3.13a. Releases by Chemical

Seventeen of the 70 chemicals released by NYS natural gas compressor stations are associated with musculoskeletal system and connective tissue diseases (ICD-10 Chapter 13). Releases of these toxicants were reported by all 18 stations and totaled an estimated 1.2 million pounds from 2008 to 2014--an annual average of 3.9 million pounds.

Chemicals associated with musculoskeletal system and connective tissue diseases represented 3.1% of releases by the state's natural gas compressor stations.

PM 2.5 ranked first with 1.1 million pounds or 92.6% of the total, followed by benzene (21,241 pounds or 1.8%) and methanol (19,333 pounds or 1.6%). These three chemicals accounted for 96% of all releases.

Table 3.13a.

### 3.13b. Releases by ICD Category

Musculoskeletal system and connective tissue diseases are subdivided into 7 major groups. Chemicals released by natural gas compressor stations in NYS are positively associated with 5 of them. It should be remembered, that a single chemical can be associated with more than one category of disease.

**M00-M25:** A single chemical released by 5 stations is associated with arthropathies, specifically, "Kashin-Beck disease".

**M30-M36:** Three chemicals released by all 18 sites are associated with systemic connective tissue disorders: undifferentiated connective tissue disease (UCTD) and connective tissue disease (CTD).

**M60-M79:** Twelve chemicals released by all 18 sites are associated with soft tissue disorders: muscle contractility, spasticity or weakness.

**M80-M90:** The heavy metal cadmium, released by 9 sites, is associated with osteopathies.

**M95-M99:** Three chemicals are associated with other disorders of the musculoskeletal system and connective tissue

### 3.13c. Releases by Facility

All natural gas compressor stations in NYS reported releases chemical associated with musculoskeletal system and connective tissue diseases.

The top 5 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 211,513 pounds or 17.2% of the state total, followed by Compressor Station 249 in Carlisle (196,907 pounds or 16%) and Compressor Station 229 in Eden (170,674 pounds or 13.8%). These three facilities were responsible for one-half of the state total.

The top 5 facilities were responsible for slightly less than two-thirds (65.1%) of all releases.

The facility average was 68,510 million pounds over 7 years or 9,787 each year.

### 3.13d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with musculoskeletal system and connective tissue diseases.

Region 9, Western New York ranked first with 316,000 pounds (25.7%), followed by Region 6, Western Adirondacks/Eastern Lake Ontario (219,490 pounds or 17.8%) and Region 4, Capital Region/Northern Catskills (257,583 or 21%).

### 3.13e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals linked to musculoskeletal system and connective tissue diseases.

Erie County ranked first with 233,139 pounds or 19% of the state total, followed by Herkimer County (219,490 pounds or 17.8%) and Schoharie County (196,906 pounds or 16%). These three counties are responsible for slightly more than one-half (53%) of all toxic releases.

The top five counties were responsible for 71%.

The country average was 87,934 pounds over a 7-year period or 12,562 pounds annually.

Table 3.13e.

## 3.14. Diseases of the Genitourinary System (N00-N99)

### 3.14a. Releases by Chemicals

Forty-three of the 70 chemicals released by NYS natural gas compressor stations are associated with diseases of the genitourinary system (ICD-10, Chapter 14).

Releases of genitourinary toxicants were reported by all 18 stations and totaled an estimated 39.7 million pounds from 2008 to 2014--an annual average of 5.7 million pounds.

Chemicals associated with genitourinary system diseases represented 99.4% of releases by the state's natural gas compressor stations.

Or, to put it differently, ***of the 40.2 million pounds of chemicals released by NYS's compressor stations, 98.9% had one or more effects on the genitourinary system.***

Nitrogen oxides ranked first with 18.1 million pounds or nearly one-half (45.5%) of the total, followed by carbon monoxide (12.4 million pounds or 31.1%) and volatile organic compounds (4.9 million pounds or 12.4%). These three chemicals accounted for 35.4 million pounds or 89% of all releases.

The top 10 chemicals accounted for 99.9% of the state total.

Table 3.14a.

### 3.14b. Releases by ICD Category

Genitourinary system diseases are subdivided into 2 major groups. Chemicals released by natural gas compressor stations in NYS are positively associated with both. It should be remembered, that a single chemical can be associated with more than one category of disease.

#### **N00-N39: Diseases of the urinary system**

Thirty-three chemicals are associated with diseases of the urinary system.

One chemical has been implicated in renal failure (N17-N19).

N25-N29: Thirty-two chemicals are associated with other disorders of kidney and ureter. Effects on kidneys include: changes in blood vessels or in circulation, permanent damage, depressed function, necrosis, stones, injury, lesions or weight change.

N30-N39: Six chemicals are associated with other diseases of urinary system, including damage to the Cowper's gland and bladder weight change.

#### **N40-N99: Diseases of the pelvis, genitals and breasts**

Thirty-seven chemicals are associated with diseases of the pelvis, genitals and breasts that effect reproduction.

Twenty-two chemicals are associated with diseases of male genital organs (N40-N51), including: epididymis, low hormone levels, male impotence, reduced fertility, semen (chemical contamination of semen, low amount of semen and low number of swimming semen), seminal vesicle injury, sperm (abnormalities, irregular shape and low number), and sterility.

A single chemical has been implicated in inflammatory diseases of female pelvic organs (N70-N77).

Nineteen have been connected to noninflammatory disorders of female genital tract (N80-N98): both primary infertility (infertility without any previous pregnancy) and secondary infertility (fertility problems occurring in a couple that has conceived on their own and had a child in the past), cervical erosion, effects on the ovaries (damage, weight changes and unspecified effects), menstrual problems including dysmenorrhea, endometrial stromal polyps, and vagina effects.

### 3.14c. Releases by Facility

All natural gas compressor stations in NYS reported releases chemical associated with genitourinary system diseases.

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 10.4 pounds, more than one-half (26.1%) of the state total, followed by Compressor Station 229 in Eden (5.1 million or 12.7%) and Compressor Station 249 in Carlisle (4.3 pounds or 10.8%). In aggregate, these three facilities were responsible for 19.8 million pounds or slightly less than one-half (49.6%) of the state total.

The top 5 facilities were responsible for 25.2 million pounds, slightly less than two-thirds (63.1%) of all releases.

The facility average was 2.2 million pounds over 7 years or 317,048 pounds each year.

### 3.14d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with genitourinary system diseases.

Region 9, Western New York ranked first with 2.7 million pounds (29.1%), closely followed by Region 6, Western Adirondacks/Eastern Lake Ontario (10.7 million pounds or 27%). Region 4, Capital Region/Northern Catskills, ranked third with 6.7 million pounds (16.8%).

### 3.14e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals linked to genitourinary system diseases.

Herkimer County ranked first with 10.7 million pounds, more than one-quarter (27%) of the state total, followed by Erie County (6.8 million pounds or 17.2%) and Schoharie County (4.3 million pounds or 10.8%). These three counties are responsible for slightly more than one-half (53%) of all toxic releases.

The top five counties were responsible for 21.8 million pounds or more than one-half (55%) of the state total.

The country average was 2.8 million pounds over a 7-year period or 405,516 pounds annually.

Table 3.14e.

## 3.15. Pregnancy, Childbirth and the Puerperium (O00-O99)

### 3.15a. Releases by Chemical

Eighteen of the 70 chemicals released by NYS natural gas compressor stations are associated with diseases of pregnancy, childbirth and the puerperium (ICD-10, Chapter 15).

Releases of these toxicants were reported by all 18 stations and totaled an estimated 19.5 million pounds from 2008 to 2014--an annual average of 2.8 million pounds.

Chemicals associated with diseases of pregnancy, childbirth and the puerperium represented 48.8% of releases by the state's natural gas compressor stations.

Or, to put it differently, ***of the 40.2 million pounds of chemicals released by NYS's compressor stations, slightly less than one-half (48.62%) had adverse effects on pregnancy, childbirth and the puerperium.***

Nitrogen oxides ranked first with 18.1 million pounds or (92.5%) of the total. Formaldehyde was a distant second (1.3 million pounds or 6.7%), followed by acetaldehyde (65,969 pounds or 0.34%).

These two chemicals accounted for 19.4 million pounds or 99.2% of all releases.

Table 3.15a.

### 3.15b. Releases by ICD Category

Diseases of pregnancy, childbirth and the puerperium are subdivided into 8 major groups. Chemicals released by natural gas compressor stations in NYS are positively associated with three. It should be remembered, that a single chemical can be associated with more than one category of disease.

O00-O08: Fourteen chemicals, released by all 18 sites, are associated with pregnancy with abortive outcome.

O30-O48: Five chemicals are associated with maternal care related to the fetus and amniotic cavity and possible delivery problems.

O85-O92: A single chemicals is implicated in complications predominantly related to the puerperium.

Table 3.15b.

### 3.15c. Releases by Facility

All natural gas compressor stations in NYS reported chemical releases associated with pregnancy, childbirth and the puerperium diseases.

The top 4 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 6.1 pounds (30.9%), followed by Compressor Station 229 in Eden (3.3 million or 16.9%) and Compressor Station 249 in Carlisle (1.9 million pounds or 9.5%). In aggregate, these three facilities were responsible for 11.2 million pounds, more than one-half (57.3%) of the state total.

The top 5 facilities were responsible for 13.4 million pounds, slightly more than two-thirds (68.4%) of all releases.

The facility average was 1.1 million pounds over 7 years or 155,768 pounds each year.

### 3.15d. Releases by DEC Regions

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with pregnancy, childbirth and the puerperium diseases.

Region 6, Western Adirondacks/Eastern Lake Ontario, ranked first with 6.2 million pounds, nearly one-half (46.3%) of the state total, closely followed by Region 9, Western New York (5.7 million pounds or 43.7%). Region 4, Capital Region/Northern Catskills, ranked third with 3 million pounds (14%).

### 3.15e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals linked to genitourinary system diseases.

Herkimer County ranked first with 6.2 million pounds, slightly less than one-third (31.7%) of the state total, followed by Erie County (4.1 million pounds or 20.9%) and Schoharie County (1.9 million pounds or 9.6%). These three counties are responsible for 12.1 million pounds (62.1%) of all toxic releases.

The top five counties were responsible for 14.3 million pounds or nearly three-fourths (73.3%) of the state total.

The country average was 1.4 million pounds over a 7-year period or 199,396 pounds annually.

Table 3.15e.

## 3.16. Certain Conditions Originating in the Perinatal Period (P00-P96)

### 3.16a. Releases by Chemical

Twenty of the 70 chemicals released by NYS natural gas compressor stations are associated with Certain Conditions Originating in the Perinatal Period (ICD-10, Chapter 16).

Releases of these toxicants were reported by all 18 stations and totaled an estimated 22.4 million pounds from 2008 to 2014--an annual average of 3.2 million pounds.

Or, to put it differently, ***of the 40.2 million pounds of chemicals released by NYS's compressor stations, 56% have been associated with certain conditions originating in the perinatal period.***

Nitrogen oxides ranked first with 18.1 million pounds, more than three-fourths (80.7%) of the total. Formaldehyde was a distant second (1,309,336 pounds or 5.8%), followed by PM 10 (1,259,744 million pounds or 3.8%). These three chemicals accounted for 19.4 million pounds or 92% of all releases.

The top 10 chemicals were responsible for virtually all releases (99.5%).

The annual average release was 3.2 million pounds.

Table 3.16a.

### 3.16b. Releases by ICD Category

Certain Conditions Originating in the Perinatal Period are subdivided into 10 major groups. Chemicals released by natural gas compressor stations in NYS are positively associated with three. It should be remembered, that a single chemical can be associated with more than one category of disease.

**P05-P08:** Twenty-one chemicals are associated with disorders related to length of gestation and fetal growth: birth weight (low or extremely low), growth statistics (e.g., reduced weight gain), preterm birth, and small for gestational age.

**P50-P61:** A single chemical has been connected to hemorrhagic and hematological disorders of fetus and newborn.

Table 3.16b.

### 3.16c. Releases by Facility

All natural gas compressor stations in NYS reported chemical releases associated with certain conditions originating in the perinatal period.

Six of the 7 top polluters were facilities operated by the Tennessee Gas Pipeline Company, including the top 4.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 6.6 million pounds (29.3%), followed by Compressor Station 229 in Eden (3.7 million pounds or 16.4%) and Compressor Station 249 in Carlisle (2.4 million pounds or 10.5%). In aggregate, these three facilities were responsible for 17.9 million pounds, slightly more than one-half (50.9%) of the state total.

The top 5 facilities were responsible for 22.5 million pounds, slightly less than two-thirds (66%) of all releases.

The facility average was 2 million pounds over 7 years or 278,879 pounds each year.

Table 3.16c.

### 3.16d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with certain conditions originating in the perinatal period.

Region 6, Western Adirondacks/Eastern Lake Ontario, ranked first with 6.7 million pounds (30.1%), closely followed by Region 9, Western New York (6.4 million pounds or 28.6%). Region 4, Capital Region/Northern Catskills, ranked third with 3.6 million pounds (16.3%).

### 3.16e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals linked to certain conditions originating in the perinatal period.

Herkimer County ranked first with 9.8 million pounds, (28%) of the state total, followed by Erie County (6.3 million pounds or 18.1%) and Schoharie County (3.6 million pounds or 10.4%). These three counties are responsible for 19.7 million pounds (56.4%) of all toxic releases.

The top five counties were responsible for 24.5 million pounds or 70% of the state total.

The country average was 2.5 million pounds over a 7-year period or 356,756 pounds annually.

Table 3.16e.

## 17. Congenital Malformations, Deformations & Chromosomal Abnormalities (Q00-Q99)

### 3.17a. Releases by Chemical

The relationship between chemical exposures in utero and during the early postnatal period and adverse health effects has been well documented.

“Epidemiological studies have shown that children's exposure to air pollutants during fetal development and early postnatal life is associated with many types of health problems including abnormal development (low birth weight [LBW], very low birth weight [VLBW], preterm birth [PTB], intrauterine growth restriction [IUGR], congenital defects, and intrauterine and infant mortality), decreased lung growth, increased rates of respiratory tract infections, childhood asthma, behavioral problems, and neurocognitive decrements.” (Wang and Pinkerton 2007).

Fifty-nine of the 70 chemicals released by NYS natural gas compressor stations are associated with congenital malformations, deformations and chromosomal abnormalities (ICD-10, Chapter 17).

Releases of these toxicants were reported by all 18 stations and totaled an estimated 39.4 million pounds from 2008 to 2014--an annual average of 5.6 million pounds.

Or, to put it differently, ***of the 40.2 million pounds of chemicals released by NYS's compressor stations, 98% have been associated with congenital malformations, deformations and chromosomal abnormalities.*** Nitrogen oxides ranked first with 18.1 million pounds, slightly less than one-half (45.9%) of the state total. Carbon monoxide was second (12.4 million pounds or 31.3%), followed by volatile organic compounds (4.9 million pounds or 12.5%). These three chemicals accounted for 35.4 million pounds or 89.7 of all releases.

The top 10 chemicals were responsible for virtually all releases (99.8%). The annual average release was 5.6 million pounds.

Table 3.17a.

### 3.17b. Releases by ICD Category

Congenital malformations, deformations & chromosomal abnormalities into 2 major disease categories. Chemicals released by natural gas compressor stations in NYS are positively associated with both.

It should be remembered, that a single chemical can be associated with more than one subcategory of disease within an ICD disease group (chapter) as well as with more than one disease group.

#### Q00-Q89: Congenital Malformation and Deformations

Fifty-seven chemicals are associated with congenital malformation and deformations. This includes:

Q00-Q07: Sixteen chemicals associated with nervous system malformations and deformations, including: brain abnormalities and defects (anencephaly, holoprosencephaly, microcephaly), CNS abnormalities and defects, cognitive developmental delay with greater language impairment, cognitive function, lower IQ, neural tube defects (opening to the spinal cord at the base of the brain), neurological impairment, spatial memory function impairment, and spina bifida.

Q10-Q18: Four chemicals are associated with eye, ear, face and neck malformations and deformations: ear abnormalities, eye abnormalities (anophthalmia and cataracts), facial clefts, and gross facial agenesis.

Q20-Q28: Ten chemicals are associated with circulatory system malformations and deformations, including

### 3.17c. Releases by Facility

All natural gas compressor stations in NYS reported chemical releases associated with congenital malformations, deformations & chromosomal abnormalities.

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 10.4 million pounds, more than one-quarter (26.2%) of the state total. Compressor Station 229 in Eden ranked second (5 million pounds or 12.7%) followed by Compressor Station 249 in Carlisle (4.2 million pounds or 10.7%). In aggregate, these three facilities were responsible for 19.7 million pounds, slightly less than one-half (49.6%) of the state total.

The top 5 facilities were responsible for 25 million pounds, slightly less than two-thirds (63.1%) of all releases.

The facility average was 2.1 million pounds over 7 years or 314,643 pounds each year.

Table 3.17c.

### 3.17d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with congenital malformations, deformations and chromosomal abnormalities.

Region 9, Western New York, ranked first with 11.5 million pounds (29.2%), closely followed by Region 6, Western Adirondacks/Eastern Lake Ontario (10.7 million pounds or 27.1%). Region 4, Capital Region/Northern Catskills, ranked third with 6.7 million pounds (16.7%).

### 3.17e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals linked to congenital malformations, deformations & chromosomal abnormalities.

Herkimer County ranked first with 10.7 million pounds or (27%) of the state total, followed by Erie County (6.8 million pounds or 17.1%) and Schoharie County (4.2 million pounds or 10.7%). These three counties are responsible for 21.7 million pounds (56.4%) of all toxic releases.

The top five counties were responsible for 27.4 million pounds or more than two-thirds (69.34) of the state total.

The country average was 2.8 million pounds over a 7-year period or 402,433 pounds annually.

## 3.18. Symptoms, Signs and Abnormal Clinical and Laboratory Findings (R00-R99)

### 3.18a. Releases by Chemicals

Forty-three of the 70 chemicals released by NYS natural gas compressor stations are associated with congenital malformations, deformations and chromosomal abnormalities (ICD-10, Chapter 18).

Releases of these toxicants were reported by all 18 stations and totaled an estimated 39.4 million pounds from 2008 to 2014--an annual average of 5.6 million pounds.

Or, to put it differently, ***of the 40.2 million pounds of chemicals released by NYS's compressor stations, 98% have been associated with symptoms, signs and abnormal clinical and laboratory findings.***

Nitrogen oxides ranked first with 18.1 million pounds, slightly less than one-half (45.9%) of the state total. Carbon monoxide was second (12.4 million pounds or 31.3%), followed by volatile organic compounds (4.9 million pounds or 12.5%). These three chemicals accounted for 35.4 million pounds or 89.7 of all releases.

The top 10 chemicals were responsible for virtually all releases (99.8%).

The annual average release was 5.6 million pounds.

Table 3.18a.

### 3.18b. Releases by ICD Category

Symptoms, signs and abnormal clinical and laboratory findings into 3 major disease categories. Chemicals released by natural gas compressor stations in NYS are positively associated with two.

It should be remembered, that a single chemical can be associated with more than one subcategory of disease within an ICD disease group (chapter) as well as with more than one disease group.

#### **R00-R69: Symptoms and signs**

Forty-two chemicals are associated with symptoms, signs and abnormal clinical and laboratory findings. This includes:

**R00-R09:** Thirty chemicals are associated with circulatory and respiratory system symptoms: changes in blood pressure, chest discomfort (burning sensation, constriction, pain), dyspnea, epistaxis, heart palpitations, heart rate (bradycardia, tachycardia), phlegm, pulse rate decrease without fall in blood pressure, pulse rate increase without fall in blood pressure, and wheezing.

**R10-R19:** Twenty-eight chemicals associated with digestive system and abdomen symptoms: abdomen (colic, cramps and pain), nausea or vomiting, and unspecified liver effects.

**R20-R23:** Thirty-two chemicals are associated with skin and subcutaneous tissue symptoms: skin (burning sensation, cracking, discoloration, pain, paresthesia, and rash), numbness in extremities, and a tingling sensation.

**R30-R39:** One chemical is associated with urinary system symptoms.

**R40-R46:** Thirty-four chemicals are associated with cognition, perception, emotional state and behavior: R40 (drowsiness, dizziness, somnolence), R41 (amnesia, confusion, memory disturbances, impairment and loss, mental confusion), R42 (dizziness, giddiness), R42 (lightheadedness and vertigo), R43 (anosmia, olfactory fatigue and unspecified effects), R43 (metallic or unpleasant taste in mouth), R45 (agitation or irritability), and R53 (lethargy).

**R47-R49:** Four chemicals are associated with speech and voice symptoms: R47 (speech (difficulties, disorders and impairment), and R49 (voice loss and disturbances).

**R50-R69:** Thirty-five chemicals are associated with general symptoms and signs: R50 (fever), R51 (headache), R53 (asthenia, alteration of classical conditioning, fatigue, listlessness, malaise, weakness), R55 (lowered consciousness), R56 (convulsions), R61 (diaphoresis), R63 (loss or decreased weight gain), R63 (altered fluid and food intake), R68 (chills), and R68 (decreased libido).

#### **R70-R94: Abnormal clinical and laboratory findings, not elsewhere classified**

Five chemicals are associated with abnormal clinical and laboratory findings, not elsewhere classified.

Table 3.18b.

### 3.18c. Releases by Facility

All natural gas compressor stations in NYS reported chemical releases associated with symptoms, signs and abnormal clinical and laboratory findings.

The top 6 polluters were facilities operated by the Tennessee Gas Pipeline Company.

Tennessee Gas Pipeline Company Compressor Station 245, ranked first with 10.4 million pounds, more than one-quarter (26.2%) of the state total. Compressor Station 229 in Eden ranked second (5. million pounds or 12.7%) followed by Compressor Station 249 in Carlisle (4.2 million pounds or 10.7%). In aggregate, these three facilities were responsible for 19.7 million pounds, slightly less than one-half (49.6%) of the state total.

The top 5 facilities were responsible for 25 million pounds, slightly less than two-thirds (63.1%) of all releases.

The facility average was 2.1 million pounds over 7 years or 314,652 pounds each year.

### 3.18d. Releases by DEC Region

The 18 compressor stations analyzed are in 6 of New York State's 9 DEC regions. All 6 regions had releases of chemicals associated with symptoms, signs and abnormal clinical and laboratory findings.

Region 9, Western New York, ranked first with 11.5 million pounds (29.2%), closely followed by Region 6, Western Adirondacks/Eastern Lake Ontario (10.7 million pounds or 27.1%). Region 4, Capital Region/Northern Catskills, ranked third with 6.7 million pounds (16.7%).

### 3.18e. Releases by County

All 14 counties where compressor stations are located reported releases of chemicals associated with symptoms, signs and abnormal clinical and laboratory findings.

Herkimer County ranked first with 10.7 million pounds or (27%) of the state total, followed by Erie County (6.8 million pounds or 17.1%) and Schoharie County (4.2 million pounds or 10.7%). These three counties are responsible for 21.7 million pounds (54.9%) of all toxic releases.

The top five counties were responsible for 27.4 million pounds or more than two-thirds (69.4%) of the state total.

The country average was 2.8 million pounds over a 7-year period or 402,444 pounds annually.

## Chapter 4. Facility Profiles

Sources:

New York State Department of Environmental Conservation, U.S. Energy Information Administration, U.S. EPA Envirofacts, U.S. EPA National Emissions Inventory

\* System Configuration - natural gas pipeline system design layout. Some systems are a combination of the trunk and grid. Where two are shown, the first represents the predominant system design.

Trunk - systems are large-diameter long-distance trunklines that generally tie supply areas to natural gas market areas.

Grid - systems are usually a network of many interconnections and delivery points that operate in and serve major natural gas market areas

## 4.14. TGPC Compressor Station 237 (Manchester, Phelps NY)

### 4.14a. Facility Profile

Table 4.14a.

#### TGPC Compressor Station 237

Manchester, Phelps NY

Facility name, short	TGPC Compressor Station 237
Facility name, full	TGPC CS 237
EIS Facility ID	7210411
DEC Region	8 -- Western Finger Lakes
County	Ontario
Town	Manchester, Phelps
Village \ Hamlet	Clifton Springs
Address	2001 Archer Road
Zip	14432
DEC Permit Type	Air Title V Facility
DEC Facility ID	323400013
DEC Permit ID	8-3234-00013/00011
DEC Permit Effective Date	6/14/2016
DEC Permit Description	Renewal of the Title V Facility Permit originally issued November 23, 1999 and previously renewed October 4, 2010.
DEC Permit Review Report	
Company	Tennessee Gas Pipeline Company
Project	Part of the Niagara Expansion Project by TGP/Kinder Morgan, which is related to National Fuel's Northern Access Project.
Pipeline	Tennessee Gas Pipeline
Principal Supply Source	
System Configuration (Primary/Secondary)	
Status	Operational
Horsepower, existing	8,000
	(1) 4,000 HP reciprocating ngfce, (2) 2,000 HP reciprocating ngfce

## 4.17. TGPC Compressor Station 249 (Carlisle NY)

### 4.17a. Facility Profile

Table 4.17a.

#### TGPC Compressor Station 249

Carlisle NY

Facility name, short	TGPC Compressor Station 249
Facility name, full	TGPC CS 249
EIS Facility ID	8435311
DEC Region	4
County	Schoharie
Town	Carlisle
Village \ Hamlet	
Address	2480 US Route 20
Zip	12031
DEC Permit Type	Air Title V Facility
DEC Facility ID	4432400005
DEC Permit ID	4-4324-00005/00007
DEC Permit Effective Date	11/6/2015
DEC Permit Description	Renewal of the Title V permit.
DEC Permit Review Report	
Company	Tennessee Gas Pipeline Company
Project	Part of the Niagara Expansion Project by TGP/Kinder Morgan, which is related to National Fuel's Northern Access Project.
Pipeline	Tennessee Gas Pipeline
Principal Supply Source	
System Configuration (Primary/Secondary)	
Status	Operational
Horsepower, existing	9,100 HP
Total estimated releases (2008-2014): pounds	
Total estimated releases (2008-2014): rank	

## 4.17b. Health Effects of Facility Releases

Table 4.18a.

#### TGPC Compressor Station 254

Chatham NY

Facility name, short	TGPC Compressor Station 254
Facility name, full	TGPC CS 254
EIS Facility ID	8525311
DEC Region	4
County	Columbia
Town	Chatham
Village \ Hamlet	Riders-Mills
Address	ST Rte 66 -- E Side S of County Line
Zip	12123
DEC Facility ID	4102600037
DEC Permit Type	Air Title V Facility
DEC Permit ID	4-1026-00037/00029
DEC Permit Effective Date	8/11/2014
DEC Permit Description	
DEC Permit Review Report	
Company	Tennessee Gas Pipeline Company
Project	Part of the Niagara Expansion Project by TGP/Kinder Morgan, which is related to National Fuel's Northern Access Project.
Pipeline	Tennessee Gas Pipeline
Principal Supply Source	
System Configuration (Primary/Secondary)	
Status	Operational
Horsepower, existing	10,475
	(1) gas turbine, (6) reciprocating engines

# Low-Concentration PM<sub>2.5</sub> and Mortality: Estimating Acute and Chronic Effects in a Population-Based Study

Lihua Shi,<sup>1</sup> Antonella Zanobetti,<sup>1</sup> Itai Kloog,<sup>1,2</sup> Brent A. Coull,<sup>3</sup> Petros Koutrakis,<sup>1</sup> Steven J. Melly,<sup>1</sup> and Joel D. Schwartz<sup>1</sup>

<sup>1</sup>Department of Environmental Health, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; <sup>2</sup>Department of Geography and Environmental Development, Ben-Gurion University of the Negev, Beer Sheva, Israel; <sup>3</sup>Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA

**BACKGROUND:** Both short- and long-term exposures to fine particulate matter ( $\leq 2.5 \mu\text{m}$ ; PM<sub>2.5</sub>) are associated with mortality. However, whether the associations exist at levels below the new U.S. Environmental Protection Agency (EPA) standards (12  $\mu\text{g}/\text{m}^3$  of annual average PM<sub>2.5</sub>, 35  $\mu\text{g}/\text{m}^3$  daily) is unclear. In addition, it is not clear whether results from previous time series studies (fit in larger cities) and cohort studies (fit in convenience samples) are generalizable.

**OBJECTIVES:** We estimated the effects of low-concentration PM<sub>2.5</sub> on mortality.

**METHODS:** High resolution (1 km  $\times$  1 km) daily PM<sub>2.5</sub> predictions, derived from satellite aerosol optical depth retrievals, were used. Poisson regressions were applied to a Medicare population ( $\geq 65$  years of age) in New England to simultaneously estimate the acute and chronic effects of exposure to PM<sub>2.5</sub>, with mutual adjustment for short- and long-term exposure, as well as for area-based confounders. Models were also restricted to annual concentrations  $< 10 \mu\text{g}/\text{m}^3$  or daily concentrations  $< 30 \mu\text{g}/\text{m}^3$ .

**RESULTS:** PM<sub>2.5</sub> was associated with increased mortality. In the study cohort, 2.14% (95% CI: 1.38, 2.89%) and 7.52% (95% CI: 1.95, 13.40%) increases were estimated for each 10- $\mu\text{g}/\text{m}^3$  increase in short- (2 day) and long-term (1 year) exposure, respectively. The associations held for analyses restricted to low-concentration PM<sub>2.5</sub> exposure, and the corresponding estimates were 2.14% (95% CI: 1.34, 2.95%) and 9.28% (95% CI: 0.76, 18.52%). Penalized spline models of long-term exposure indicated a larger effect for mortality in association with exposures  $\geq 6 \mu\text{g}/\text{m}^3$  versus those  $< 6 \mu\text{g}/\text{m}^3$ . In contrast, the association between short-term exposure and mortality appeared to be linear across the entire exposure distribution.

**CONCLUSIONS:** Using a mutually adjusted model, we estimated significant acute and chronic effects of PM<sub>2.5</sub> exposure below the current U.S. EPA standards. These findings suggest that improving air quality with even lower PM<sub>2.5</sub> than currently allowed by U.S. EPA standards may benefit public health.

**CITATION:** Shi L, Zanobetti A, Kloog I, Coull BA, Koutrakis P, Melly SJ, Schwartz JD. 2016. Low-concentration PM<sub>2.5</sub> and mortality: estimating acute and chronic effects in a population-based study. *Environ Health Perspect* 124:46–52; <http://dx.doi.org/10.1289/ehp.1409111>

## Introduction

Many studies have found associations between fine particulate matter [PM with aerodynamic diameter  $\leq 2.5 \mu\text{m}$  (PM<sub>2.5</sub>)] and increased mortality (Dockery et al. 1993; Franklin et al. 2007; Pope et al. 2002; Schwartz 1994; Zanobetti and Schwartz 2009). Biological evidence has been established for plausible mechanisms between PM<sub>2.5</sub> and mortality, such as increased risk of ventricular arrhythmia and thrombotic processes, increased system inflammation and oxidative stress, increased blood pressure, decreased plaque stability, and reduced lung function, among others (Brook et al. 2009; Gauderman et al. 2004; Gurgueira et al. 2002; Suwa et al. 2002; Yue et al. 2007). Based on evidence from epidemiological and toxicological studies (Chen and Nadziejko 2005; Furuyama et al. 2006; Ohtoshi et al. 1998), National Ambient Air Quality Standards (NAAQS) were implemented for fine particulate matter. For example, the U.S. Environmental Protection Agency (EPA) revised the fine particle NAAQS in 1997, 2006, and 2012 in order to protect public

health (U.S. EPA 1997, 2006, 2013). Further changes in the standards require additional studies to elucidate whether health effects occur at levels below the current annual and daily U.S. EPA NAAQS of 12 and 35  $\mu\text{g}/\text{m}^3$ , respectively. The Clean Air Act Amendments of 1990 require the U.S. EPA to review national air quality standards every 5 years to determine whether they should be retained or revised; thus, whether health effects can be observed below the current standards is of great interest and importance.

Previous studies have generally focused on either long-term (Hart et al. 2011; Jerrett et al. 2005; Puett et al. 2009; Schwartz 2000) or short-term (Dominici et al. 2006; Katsouyanni et al. 1997; Samoli et al. 2008; Schwartz and Dockery 1992) exposures across the entire range of PM<sub>2.5</sub> concentrations. In the case of time series analyses of short-term exposures, the need to ensure the relevance of the monitoring data as well as the need to have a study population of a size for sufficient power has limited analyses to large cities; hence, exurbs, small cities, and

rural areas are not generally represented in the literature, which may compromise the generalizability of the results. In addition, there is spatial variability in PM<sub>2.5</sub> concentrations within cities that time series studies generally do not take into account, which can introduce exposure measurement error (Laden et al. 2006; Lepeule et al. 2012).

Chronic effects studies began using comparisons across cities of mortality experiences of cohorts living in various communities and the monitored air pollutant concentrations in those communities (Dockery et al. 1993; Pope et al. 1995). Again, these studies suffered from exposure error due to failure to capture within-city spatial variability in exposure. Because the geographic exposure gradient is the exposure contrast in these studies, the failure to capture within-city contrasts leads to classical measurement error with expected downward bias. Studies with, for example, land use regression estimates of exposure have generally reported larger effect sizes (Miller et al. 2007; Puett et al. 2009). Previous cohort studies have not controlled for the acute effects of particles when estimating chronic effects, raising the question of whether there are independent chronic effects that represent more than the cumulative effects of acute responses.

In general, existing study cohorts are not representative of the overall population. For example, the American Cancer Society (ACS) cohort has a higher level of education than the U.S. population as a whole (Stellman

and Garfinkel 1986). Hence, few population-based cohort studies have been conducted until recently (Kloog et al. 2013).

Several time series studies examined the concentration–response relationship between PM<sub>2.5</sub> and mortality below concentrations of 100 µg/m<sup>3</sup>; these studies generally reported a linear concentration–response relationship (Samoli et al. 2008; Schwartz and Zanobetti 2000). However, there have been few studies focusing on exposures below the current daily U.S. EPA standard of 35 µg/m<sup>3</sup>.

Many studies have examined the shape of the concentration–response curve for long-term exposure versus short-term exposure, but in general, they have not covered population-based cohorts, or have only included very low exposures (Schwartz et al. 2008; Crouse et al. 2012).

We recently presented a new hybrid method of assessing temporally and spatially resolved PM<sub>2.5</sub> exposure for epidemiological studies by combining 1 km × 1 km resolution satellite-retrieved aerosol optical depth (AOD) measurements with traditional land use terms, meteorological variables, and their interactions (Kloog et al. 2014a). This approach allows for predicting daily PM<sub>2.5</sub> concentrations at a 1 km × 1 km spatial resolution throughout the New England area of the northeastern United States. We also validated our model's performance in rural areas: 10-fold cross-validation (CV) of our model in rural areas (using the IMPROVE stations)

resulted in a CV  $R^2$  of 0.92. Further details have been published (Kloog et al. 2014a).

The present study aimed to simultaneously estimate acute and chronic health effects of PM<sub>2.5</sub> in a population-based Medicare cohort (≥ 65 years of age) encompassing the New England region. We used high-spatial-resolution exposure estimates based on satellite measurements that are available across the region and not just in limited locations. To make this study relevant to future assessments of current U.S. EPA standards, we repeated the analysis after restricting the data to long-term exposures (365-day moving average) < 10 µg/m<sup>3</sup> and repeated the time series analysis of short-term exposures after restricting the data to 2-day average exposures < 30 µg/m<sup>3</sup>.

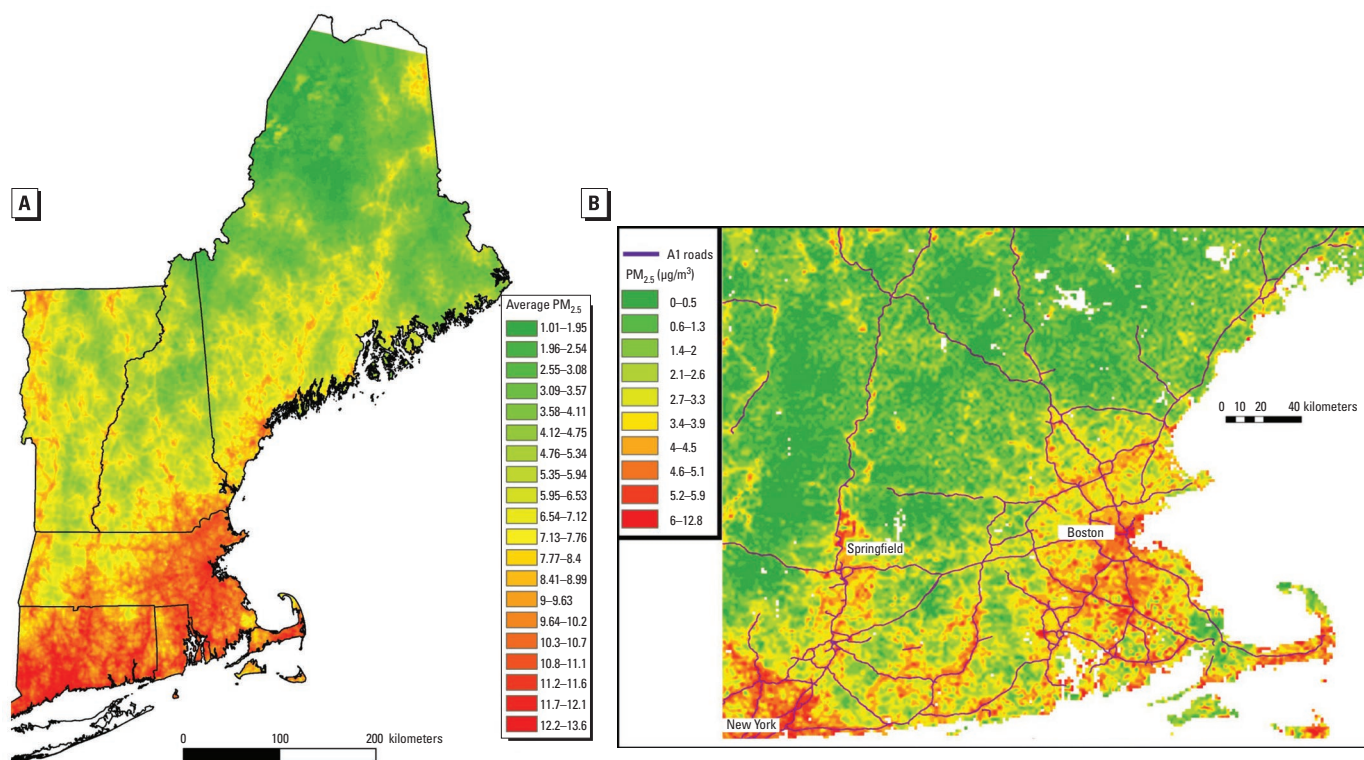

## Methods

**Study domain.** The spatial domain of our study included the New England area, comprising the states of Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, and Vermont (Figure 1A).

**Exposure data.** A 3-stage statistical modeling approach for predicting daily PM<sub>2.5</sub> was previously reported incorporating AOD and land use data for the New England region (Kloog et al. 2011). Previous studies have shown that using actual physical measurements in our prediction models improved predictive accuracy over that of comparable land use or spatial smoothing models

(Kloog et al. 2011). With AOD retrieved by the multi-angle implementation of atmospheric correction (MAIAC) algorithm, a similar approach was applied for estimating daily PM<sub>2.5</sub> exposures in New England at a spatial resolution of 1 km × 1 km (Kloog et al. 2014a). In this study, the same PM<sub>2.5</sub> exposure predictions were employed.

Briefly, we calibrated the AOD–PM<sub>2.5</sub> relationship on each day of the study period (2003–2008) using data from grid cells with both ground PM<sub>2.5</sub> monitors and AOD measurements (stage 1), and we used inverse probability weighting to address selection bias due to nonrandom missingness patterns in the AOD measurements. We then used the AOD–PM<sub>2.5</sub> relationship to predict PM<sub>2.5</sub> concentrations for grid cells that lacked monitors but had available AOD measurement data (stage 2). Finally, we used a generalized additive mixed model (GAMM) with spatial smoothing and a random intercept for each 1 km × 1 km grid cell to impute data for grid cells/days for which AOD measurements were not available (stage 3). The performance of the estimated PM<sub>2.5</sub> was validated by 10-fold cross-validation. High out-of-sample  $R^2$  ( $R^2 = 0.89$ , year-to-year variation 0.88–0.90 for the years 2003–2008) was found for days with available AOD data. Excellent performance held even in cells/days with no available AOD ( $R^2 = 0.89$ , year-to-year variation 0.87–0.91 for the years 2003–2008). The 1-km model had better spatial (0.87)

**Figure 1.** (A) Mean PM<sub>2.5</sub> concentrations in 2004 at a high resolution (1 km × 1 km) across New England predicted by the AOD models. (B) Predicted PM<sub>2.5</sub> concentrations at a 1 km × 1 km grid for 15 November 2003.

and temporal (0.87) out-of-sample  $R^2$  than the previous 10-km model (0.78 and 0.84, respectively). Details of the  $PM_{2.5}$  prediction models are in Kloog et al. (2014a).

Figure 1A shows an example of mean  $PM_{2.5}$  concentrations in 2004 at a 1 km  $\times$  1 km spatial resolution across New England. By averaging the estimated daily exposures at each location, we generated long-term exposures.

Figure 1B (a subset of the study area) shows that spatial variability existed even for daily data and was not identical to the long-term pattern shown in Figure 1A. That is, there was space–time variation in the  $PM_{2.5}$  exposure captured in this analysis, but not in previous time-series analyses.

Because the deaths were coded at the ZIP code level, both long- and short-term predictions were matched to ZIP codes by using ArcGIS (ESRI, Redlands, CA) and SAS (SAS Institute Inc., Cary, NC) to link the ZIP code centroid to the nearest  $PM_{2.5}$  grid.

Traditionally, studies of acute air pollution effects have controlled for temperature using values taken from the nearest airport. This approach is not feasible for the entire region because many residences are distant from airports. In addition, there is spatiotemporal variation in temperature. We have applied a similar 3-stage statistical modeling approach to estimate daily ambient temperature at 1 km  $\times$  1 km resolution in New England using satellite-derived surface temperature (Kloog et al. 2014b). To our knowledge, such fine control for temperature has not previously been used in air pollution epidemiology.

**Mortality data.** Individual mortality records were obtained from the U.S. Medicare program for all residents  $\geq 65$  years of age for all available years during 2003–2008 (CMS 2013b). The Medicare cohort was used because of the availability of ZIP code of residence data, whereas National Center for Health Statistics mortality data are only available at the county level. Additionally, previous studies found that elderly people are highly susceptible to the effects of particulate matter (Pope 2000). The Medicare beneficiary denominator file from the Centers for Medicare and Medicaid services (CMS 2013a) lists all beneficiaries enrolled in the Medicare fee-for-service (FFS) program and contains information on beneficiaries' eligibility and enrollment in Medicare and the date of death. The Medicare Provider Analysis and Review (MEDPAR) file includes information on age, sex, race, ZIP code of residence, and one record for each hospital admission (CMS 2013c).

Daily mortality was first aggregated by ZIP code and then matched with the corresponding  $PM_{2.5}$  exposure. We summarized the mortality data by ZIP code and day because that was the finest resolution we could obtain for addresses. Because the mortality data sets

did not include changes of residence, we assumed that the subjects lived at their current address over the entire study period.

**Covariates.** We used daily 1-km temperature data estimated from surface temperature measured by satellites (Kloog et al. 2014b). All socioeconomic variables were obtained through the U.S. Census Bureau 2000 Census Summary File 3, which includes social, economic, and housing characteristics (U.S. Census Bureau 2000). ZIP code tabulation area–level socioeconomic variables, including race, education, and median household income, were used. The county-level percentage of people who currently smoke every day, obtained from the CDC Behavioral Risk Factor Surveillance survey for the entire country, was also adjusted (CDC 2013). Dummy variables were used to control for day of the week.

**Statistical models.** Conventionally, the acute effects of air pollution are estimated by Poisson log-linear models, and the chronic effects of air pollution are estimated by Cox proportional hazard models (Kloog et al. 2013; Laden et al. 2006). Laird and Olivier (1981) noted the equivalence of the likelihood of a proportional hazard model with piecewise constant hazard for each year of follow-up and a Poisson regression with a dummy variable for each year of follow-up. We have taken advantage of this equivalence to generalize from dummy variables for each year to a spline of time to represent the baseline hazard and to aggregate subjects into counts per person time at risk, and we obtained a mixed Poisson regression model (Kloog et al. 2012). This approach allows the rate of death as a function of both long- and short-term exposures to be modeled simultaneously. By doing so, we achieved the equivalence of a separate time series analysis for each ZIP code, greatly reducing the exposure error in that part of the model, while simultaneously conducting a survival analysis on the participants, and we were also able to estimate the independent effects of both exposures.

Most time series studies have reported stronger associations with acute exposures when exposures were defined as the mean  $PM_{2.5}$  on the day of death and the previous day (lag01) than when they were defined as the mean  $PM_{2.5}$  on the current day only, or for exposures with longer lags (Schwartz et al. 1996; Schwartz 2004). We used the lag01 average for our main analysis but performed a sensitivity analysis on that choice. Long-term exposure was calculated as the 365-day moving average ending on the date of death so that our results were comparable with those of previous studies (Lepeule et al. 2012; Schwartz et al. 2008). Short-term exposure was defined as the difference between the 2-day average and the long-term average, ensuring that acute and chronic effects were

independent. We subtracted the long-term average from the short-term average to avoid collinearity issues and to ensure that differences between ZIP codes in  $PM_{2.5}$  at a given time did not contribute to the short-term effect estimate. Thus, the short-term effect could not be confounded by variables that differed across ZIP codes.

Specifically, we fit a Poisson survival analysis with a logarithmic link function and a log (population) offset term and modeled the expected daily death counts ( $\mu_{it}$ ) in the  $i$ th ZIP code on the  $t$ th day as follows:

$$\log(\mu_{it}) = \lambda_i + \beta_1 PM_{it} + \beta_2 \Delta PM_{it} + \lambda(t) + \text{temporal covariates} + \text{spatial covariates} + \text{offset}, \quad [1]$$

where  $\lambda_i$  is a random intercept for each ZIP code,  $PM_{it}$  is the 365-day moving average ending on day  $t$  in ZIP code  $i$ ,  $\Delta PM_{it}$  is the deviation of the 2-day average from its long-term average ( $PM_{it}$ ) in ZIP code  $i$ ,  $\lambda(t)$  is a smooth function of time, temporal covariates are temperature and day of the week, and spatial covariates are socioeconomic factors defined at the ZIP code level (percent of people without high school education, percent of white people, median household income) and smoking data at the county level. Additionally, a quasi-Poisson model was used to control for possible overdispersion (Ver Hoef and Boveng 2007).

We estimated  $\lambda(t)$  with a natural cubic spline with 5 degrees of freedom (df) per year to control for time and season trends. The specific temporal and spatial covariates that we used were a natural cubic spline for temperature with 3 df in total; a categorical variable for day of the week; linear variables for percent of people without high school education, percent of white people, median household income, and percent of people who currently smoke every day.

The number of deaths per ZIP code area over the study period (2003–2008) averaged 319 with a standard deviation of 430. Because the outcome was counts, we could not adjust for age and sex as in a Cox model. Instead, we adjusted for variables that varied by ZIP code. The analyses were repeated without mutual adjustment for short- and long-term  $PM_{2.5}$ .

We modeled the association between all-cause mortality and  $PM_{2.5}$  at low doses in which the person-time at risk in each year of follow-up in each ZIP code was used as the offset. We also conducted effect modification by population size by choosing the median (4,628) of the ZIP code–level total population as the cutoff between urban and rural areas.

**Estimating the effects of low-level  $PM_{2.5}$ .** For full cohort analyses with 10,938,852 person-years of follow-up, all observed deaths were used. To estimate effects at low

levels of exposure, we performed restricted analyses: we conducted one analysis restricted to annual exposures < 10 µg/m<sup>3</sup>, below the current annual PM<sub>2.5</sub> NAAQS of 12 µg/m<sup>3</sup>, and another restricted to observations with short-term exposure < 30 µg/m<sup>3</sup>, below the current daily PM<sub>2.5</sub> NAAQS of 35 µg/m<sup>3</sup>. After these exclusions, the chronic analyses were restricted to 268,050 deaths out of 551,024 deaths in total, and the acute analyses were restricted to 422,637 deaths.

**Assessing the dose–response relationship.** For both the acute and chronic analyses, we fit penalized regression splines in the restricted analyses to estimate the shape of the dose–response curve below current U.S. EPA standards. The degrees of freedom of the penalized splines for PM<sub>2.5</sub> were estimated by generalized cross-validation (GCV).

## Results

Table 1 presents a summary of the predicted exposures for both short- and long-term PM<sub>2.5</sub> exposure across all grid cells in the study area.

Table 2 presents the estimated percent change in all-cause mortality with 95% CIs for a 10-µg/m<sup>3</sup> increase in both short- and long-term PM<sub>2.5</sub> in the restricted and full cohort. In the restricted population, we found an estimated 9.28% increase in mortality (95% CI: 0.76, 18.52%) for every 10-µg/m<sup>3</sup> increase in long-term PM<sub>2.5</sub> exposure. A 2.14% increase in mortality (95% CI: 1.34, 2.95%) was observed for every 10-µg/m<sup>3</sup> increase in short-term PM<sub>2.5</sub> exposure. For long-term exposure, the effect estimates were smaller when higher pollution days were included (7.52%; 95% CI: 1.95, 13.40%), suggesting larger effects between low-concentration long-term PM<sub>2.5</sub> and mortality.

Without mutual adjustment, lower estimates were found for both acute and chronic

effects than for those with mutual adjustment. In full-cohort analyses, a 2.08% (95% CI: 1.32, 2.84%) and a 6.46% (95% CI: 0.93, 12.30%) increase in mortality was found for each 10-µg/m<sup>3</sup> increase in short- and long-term PM<sub>2.5</sub>, respectively. In restricted analyses, the corresponding effect estimates were 2.07% (95% CI: 1.27, 2.89%) and 7.16% (95% CI: –1.23, 16.27%), respectively.

Our results were robust to the choice of lag period for acute exposure. We analyzed different averaging periods (Figure 2): for example, lag0 (day of death exposure) and lag04 (a moving average of day of death exposure and previous 4-day exposure). For the acute effects, we found a significant but smaller association for lag0 PM<sub>2.5</sub> (1.71%; 95% CI: 1.09, 2.34%) and lag04 PM<sub>2.5</sub> (1.76%; 95% CI: 0.72, 2.81%) than for lag01 analysis. The lag period used for short-term exposure did not affect estimates of chronic effects. For example, estimated increases in mortality with a 10-µg/m<sup>3</sup> increase in long-term PM<sub>2.5</sub> were 7.35% (95% CI: 1.79, 13.21%) and 7.25% (95% CI: 1.69, 13.12%) when short-term PM<sub>2.5</sub> was classified using lag0 or lag04, respectively.

We also examined effect modification by population size. In the full cohort, a significant interaction was found for chronic effects ( $p < 0.01$ ), with a larger effect of 12.56% (95% CI: 5.71, 19.85%) in urban areas compared with 3.21% (95% CI: –2.92, 9.72%) in rural areas. Such a significant interaction, however, was not observed in the restricted analysis ( $p = 0.16$ ). Estimates were 14.27% (95% CI: 3.19, 26.53%) and 5.48% (95% CI: –4.21, 16.16%) in urban and rural areas, respectively. For short-term exposure, population size did not modify the acute effects in either the full cohort or the restricted analysis ( $p = 0.74$  and 0.46, respectively).

**Table 1.** Descriptive statistics for PM<sub>2.5</sub> exposure and temperature in New England, 2003–2008.

Covariate	Mean	SD	Minimum	Median	Maximum	Range	Q1	Q3	IQR
Lag01 PM <sub>2.5</sub> (µg/m <sup>3</sup> )	8.21	5.10	0.00	7.10	53.98	53.98	4.60	10.65	6.05
1-year PM <sub>2.5</sub> (µg/m <sup>3</sup> )	8.12	2.28	0.08	8.15	20.22	20.14	6.22	10.00	3.78
Temperature (°C)	9.24	6.50	–36.79	9.81	41.51	78.30	4.90	14.39	9.49

**Table 2.** Percent increase in mortality (95% CI) for a 10-µg/m<sup>3</sup> increase for both short-term and long-term PM<sub>2.5</sub>.

PM <sub>2.5</sub> exposure	Model	Percent increase	p-Value
With mutual adjustment			
Short-term PM <sub>2.5</sub>	Low daily exposure <sup>a</sup>	2.14 ± 0.81	< 0.001
	Full cohort	2.14 ± 0.75	< 0.001
Long-term PM <sub>2.5</sub>	Low chronic exposure <sup>b</sup>	9.28 ± 8.88	0.032
	Full cohort	7.52 ± 5.73	0.007
Without mutual adjustment			
Short-term PM <sub>2.5</sub>	Low daily exposure <sup>a</sup>	2.07 ± 0.80	< 0.001
	Full cohort	2.08 ± 0.76	< 0.001
Long-term PM <sub>2.5</sub>	Low chronic exposure <sup>b</sup>	7.16 ± 8.75	0.109
	Full cohort	6.46 ± 5.69	0.026

The full cohort analysis had 551,024 deaths.

<sup>a</sup>The analysis was restricted only to person time with daily PM<sub>2.5</sub> < 30 µg/m<sup>3</sup> (422,637 deaths). <sup>b</sup>The analysis was restricted only to person time with chronic PM<sub>2.5</sub> < 10 µg/m<sup>3</sup> (268,050 deaths).

In our penalized spline model for long-term exposure below the cutoff of 10 µg/m<sup>3</sup> (Figure 3A), we found a nonlinear relationship between long-term PM<sub>2.5</sub> and mortality. The association was linear with evidence of a smaller effect < 6 µg/m<sup>3</sup>. However, a large confidence interval was observed; hence, we could not be confident whether the slope of the dose–response curve changed for long-term exposures < 6 µg/m<sup>3</sup>. When examining the shape of the dose–response curve for chronic effects, both a linear term for short-term exposure (the difference) and a penalized spline for long-term average exposure were included in the model, resulting in a penalized spline with a df of 1.71. In contrast, we only included the 2-day average in the penalized spline model of acute effects in order to provide an interpretable dose–response relationship (Figure 3B). The results of this analysis indicated a linear association across the exposure distribution, but we could not be certain about the shape of the slope for acute effects < 3 µg/m<sup>3</sup>.

## Discussion

When we applied the predicted daily PM<sub>2.5</sub> with 1-km spatial resolution from our novel hybrid models, we observed that both short- and long-term PM<sub>2.5</sub> exposure were significantly associated with all-cause mortality among residents of New England ≥ 65 years of age, even when restricted to ZIP codes and times with annual exposures < 10 µg/m<sup>3</sup> or with daily exposure < 30 µg/m<sup>3</sup>. Hence, the association of particle exposure with mortality exists for concentrations below the current standards established by the United States, the World Health Organization (WHO) (10 µg/m<sup>3</sup> of annual average PM<sub>2.5</sub>, 25 µg/m<sup>3</sup> daily), and the European Union (EU) (25 µg/m<sup>3</sup> of annual average PM<sub>2.5</sub>) (EU 2013; WHO 2013). Notably, this analysis includes all areas in New England and all Medicare enrollees ≥ 65 years of age in this region, and it provides chronic effect estimates that are independent of acute effects. Based

**Figure 2.** Percent change in mortality per 10-µg/m<sup>3</sup> increase in short-term PM<sub>2.5</sub> with different lags with mutual adjustment. Error bars indicate the 95% CIs.

on a penalized spline model, the positive dose–response relationship between chronic exposure and mortality appears to be linear for  $\text{PM}_{2.5}$  concentrations  $\geq 6 \mu\text{g}/\text{m}^3$ , with a positive (though smaller and less precise) dose–response slope continuing below this level. This lack of power is likely due to the small exposed population in areas with annual  $\text{PM}_{2.5} < 6 \mu\text{g}/\text{m}^3$ , which were quite rural.

For acute effects, we found a 2.14% (95% CI: 1.38, 2.89%) increase in all-cause mortality per  $10\text{-}\mu\text{g}/\text{m}^3$  increment in  $\text{PM}_{2.5}$  for the full cohort of our study, which is higher than the effect size of most studies using city averages obtained from monitors. For instance, in a U.S. national study by Zanobetti and Schwartz (2009), the effect size was 0.98% (95% CI: 0.75, 1.22%). Similar results were also obtained in a systematic review, where researchers determined that the overall summary estimate was 1.04% (95% CI: 0.52, 1.56%) per  $10\text{-}\mu\text{g}/\text{m}^3$  increment in  $\text{PM}_{2.5}$  (Atkinson et al. 2014). The exposure data used in most previous studies had low spatial resolution (citywide average, not ZIP code), which introduced exposure measurement error and likely resulted in a downward bias in estimates; our results (for the acute effect) are consistent with such a phenomenon. Our restricted study estimated a 2.14% (95% CI: 1.34, 2.95%) increase in all-cause mortality per  $10\text{-}\mu\text{g}/\text{m}^3$  increment in  $\text{PM}_{2.5}$ , which was close to the effect size of the full cohort study, possibly because the sample size of the restricted study for acute effects was close to that of the full cohort. Furthermore, the U.S. EPA daily standard ( $35 \mu\text{g}/\text{m}^3$ ) was almost never exceeded in this study. In addition, lower effect estimates for short-term exposure were observed with mutual adjustment for both full cohort and restricted analyses. This finding has important implications for the interpretation of previous studies without such mutual adjustment.

For chronic effects, the effect estimate in our full cohort study was consistent with findings of previous studies with comparable sample sizes (Hoek et al. 2013; Laden et al. 2006; Lepeule et al. 2012). For example, an ACS study comprising 500,000 adults from 51 U.S. cities reported a 6% (95% CI: 2, 11%) increase in all-cause mortality for each  $10\text{-}\mu\text{g}/\text{m}^3$  increment in  $\text{PM}_{2.5}$  (Pope et al. 2002). A study of 13.2 million elderly Medicare recipients across the eastern United States found a 6.8% (95% CI: 4.9, 8.7%) increase in all-cause mortality for each  $10\text{-}\mu\text{g}/\text{m}^3$  increment in  $\text{PM}_{2.5}$  (Zeger et al. 2008). When we restricted our analysis to annual concentrations  $< 10 \mu\text{g}/\text{m}^3$ , a larger slope of 9.28% (95% CI: 0.76, 18.52%) increase per  $10 \mu\text{g}/\text{m}^3$  was observed. Our findings suggest a larger effect at low concentrations among those  $\geq 65$  years of age, which may also reflect particle

composition. The sources and composition of the particles may differ between low-pollution days and high-pollution days, which are likely more affected by secondary aerosols. Compared with the effect estimate for the full cohort, the effect estimate from the restricted analysis was closer to estimates published in the literature that reported larger effect estimates, such as those reported by the ESCAPE (European Study of Cohorts for Air Pollution Effects) study, the Harvard Six Cities study, and the Women's Health Initiative study (Beelen et al. 2014; Puett et al. 2008). Smaller effect estimates were also observed for chronic effects without mutual adjustment.

To the best of our knowledge, this study is the first of its kind to restrict exposure and to explore the dose–response relationship between  $\text{PM}_{2.5}$  below the current U.S. EPA standards ( $12 \mu\text{g}/\text{m}^3$  of annual average  $\text{PM}_{2.5}$ ,  $35 \mu\text{g}/\text{m}^3$  daily) and mortality. Moreover, the use of the Medicare cohort means that we studied the entire population of Medicare enrollees  $\geq 65$  years of age and not a convenience sample. In addition, temperature was controlled on a  $1 \text{ km} \times 1 \text{ km}$  fine geographic scale. The acute and chronic effects observed in analyses restricted to low  $\text{PM}_{2.5}$  exposure were similar to or even higher than those of the full cohort analyses. These results indicate that the adverse health effects of  $\text{PM}_{2.5}$  are at least retained, if not strengthened, at low levels of exposure. However, the findings from the penalized spline model did not support a strong association at the lowest range of  $\text{PM}_{2.5}$  concentrations. This finding provides epidemiological evidence for the reevaluation of U.S. EPA guidelines and standards, although more evidence is needed to confirm the association  $< 6 \mu\text{g}/\text{m}^3$ .

The Poisson survival analysis applied in this study provided a novel method of simultaneously assessing acute and chronic effects. As shown in our analysis, the chronic effect estimate was much larger than the acute effect estimate after controlling for the acute

estimate, indicating that there were chronic effects of  $\text{PM}_{2.5}$ , which cannot be solely explained by the short-term exposure.

Another key component of this study is that the application of high spatial ( $1 \text{ km} \times 1 \text{ km}$ ) and temporal (daily) resolution of  $\text{PM}_{2.5}$  concentrations reduced exposure error to a certain extent. The out-of-sample  $R^2$  was higher than that for the predictions with  $10 \text{ km} \times 10 \text{ km}$  spatial resolution.

A potential limitation is the limited availability of individual-level confounders, such as smoking status, which could bias the health effect estimates. We were able to control for ZIP code–level education, median income, race, and county-level smoking data. However, Brochu et al. (2011) reported that census tract–level socioeconomic indicators were uncorrelated with  $\text{PM}_{2.5}$  on the subregional and local scale, providing some assurance that confounding by socioeconomic status may not be much of an issue. The results reported by Brochu et al. (2011) suggest that those variables may not confound the association, but the inability to control for them remains an issue. Another limitation is that we did not examine other pollutants such as ozone ( $\text{O}_3$ ) or nitrogen dioxide ( $\text{NO}_2$ ) owing to a lack of data at the same spatial level as that of  $\text{PM}_{2.5}$ .

## Conclusions

In conclusion, the acute and chronic effects of low-concentration  $\text{PM}_{2.5}$  were examined for a Medicare population using a comprehensive exposure data set obtained from a satellite-based prediction model. Our findings show that both short- and long-term exposure to  $\text{PM}_{2.5}$  were associated with all-cause mortality, even for exposure levels not exceeding the newly revised U.S. EPA standards, suggesting that adverse health effects occur at low levels of fine particles. The policy implication of these findings is that improving the air quality at even lower levels of  $\text{PM}_{2.5}$  than presently allowed by the U.S. EPA standards can yield health benefits.

**Figure 3.** The dose–response relationship between long-term  $\text{PM}_{2.5}$  and mortality at low doses with mutual adjustment (A) and the dose–response relationship between short-term  $\text{PM}_{2.5}$  and mortality at low doses without mutual adjustment (B). Shaded areas indicate the 95% CIs.

# Estimating Causal Effects of Local Air Pollution on Daily Deaths: Effect of Low Levels

Joel Schwartz, Marie-Abele Bind, and Petros Koutrakis

Department of Environmental Health, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA

**BACKGROUND:** Although many time-series studies have established associations of daily pollution variations with daily deaths, there are fewer at low concentrations, or focused on locally generated pollution, which is becoming more important as regulations reduce regional transport. Causal modeling approaches are also lacking.

**OBJECTIVE:** We used causal modeling to estimate the impact of local air pollution on mortality at low concentrations.

**METHODS:** Using an instrumental variable approach, we developed an instrument for variations in local pollution concentrations that is unlikely to be correlated with other causes of death, and examined its association with daily deaths in the Boston, Massachusetts, area. We combined height of the planetary boundary layer and wind speed, which affect concentrations of local emissions, to develop the instrument for particulate matter  $\leq 2.5 \mu\text{m}$  ( $\text{PM}_{2.5}$ ), black carbon (BC), or nitrogen dioxide ( $\text{NO}_2$ ) variations that were independent of year, month, and temperature. We also used Granger causality to assess whether omitted variable confounding existed.

**RESULTS:** We estimated that an interquartile range increase in the instrument for local  $\text{PM}_{2.5}$  was associated with a 0.90% increase in daily deaths (95% CI: 0.25, 1.56). A similar result was found for BC, and a weaker association with  $\text{NO}_2$ . The Granger test found no evidence of omitted variable confounding for the instrument. A separate test confirmed the instrument was not associated with mortality independent of pollution. Furthermore, the association remained when all days with  $\text{PM}_{2.5}$  concentrations  $> 30 \mu\text{g}/\text{m}^3$  were excluded from the analysis (0.84% increase in daily deaths; 95% CI: 0.19, 1.50).

**CONCLUSIONS:** We conclude that there is a causal association of local air pollution with daily deaths at concentrations below U.S. EPA standards. The estimated attributable risk in Boston exceeded 1,800 deaths during the study period, indicating that important public health benefits can follow from further control efforts.

## Introduction

Starting in the late 1980s, a large literature of time series studies have reported associations of daily air pollution concentrations with daily deaths (Analitis et al. 2006; Bell et al. 2004, 2013; Carbajal-Arroyo et al. 2011; Dominici et al. 2005; Fischer et al. 2003; Krall et al. 2013; Maynard et al. 2007; Peng et al. 2013; Samoli et al. 2006; Schwartz 2004a, 2004b; Stölzel et al. 2007; Zanobetti and Schwartz 2008, 2009). The most consistent results have been that particle concentrations are associated with daily mortality.

Fewer studies have examined the effects of source-specific particle contributions or individual particle species. Several large multicity studies have reported stronger associations for particle sulfate and nickel (Bell et al. 2014; Dai et al. 2014; Franklin et al. 2008). The U.S. Environmental Protection Agency's (EPA's) recent transport regulation has already produced substantial reductions in sulfate particles, and is scheduled to reduce remaining sulfur emissions further in the next few years (U.S. EPA 2016). As the sulfate contribution to particle mass declines and  $\text{NO}_x$  (nitrogen oxides) controls affect secondary organic particle formation, local

emissions of particulate and gaseous pollutants will become a more important part of the pollution mix; thus it is important to enhance our understanding of their health impact.

The observational epidemiology studies cited above have been associational studies, which do not assess causality. In general, when arguing for the causality of observed associations, authors have relied on Hill's Criteria (Hill 1965). For example, Brook et al. (2010) state "Many potential biological mechanisms exist whereby PM exposure could exacerbate existing CVDs [cardiovascular diseases] and trigger acute cardiovascular events (over the short term) and instigate or accelerate chronic CVDs (over the long run)." Besides biological plausibility, the  $\text{PM}_{2.5}$  (particulate matter  $\leq 2.5 \mu\text{m}$ ) epidemiological studies were relatively consistent, and exposure preceded effect.

The strength of the biological plausibility argument has grown over time (Brook et al. 2004), and includes studies indicating that particle exposure can induce lung and systemic inflammation (Adamkiewicz et al. 2004; Adar et al. 2007a; Araujo 2010; Brook 2008; Driscoll 2000; Dye et al. 2001; Folkmann et al. 2007), increase blood pressure (Baccarelli

et al. 2011; Bartoli et al. 2009; Brook et al. 2009; Hoffmann et al. 2012; Schwartz et al. 2012; Wilker et al. 2010; Zanobetti et al. 2014), impair microvascular function (Brauner et al. 2008), increase coagulation and thrombosis (Baccarelli et al. 2007, 2008; Bind et al. 2012; Bonzini et al. 2010; Carlsten et al. 2007; Chuang et al. 2007; Gilmour et al. 2005; Nemmar et al. 2002), produce autonomic changes (Adar et al. 2007b; Chahine et al. 2007; Chan et al. 2004; Ghelfi et al. 2008; Zhong et al. 2015), accelerate atherosclerosis (Adar et al. 2010; Allen et al. 2009; Araujo et al. 2008; Bauer et al. 2010; Bhatnagar 2006; Hansen et al. 2007; Hoffmann et al. 2007; Sun et al. 2005, 2008; Suwa et al. 2002; Tzeng et al. 2007), and destabilize atherosclerotic plaque (Suwa et al. 2002).

There are fewer and less consistent studies assessing the effects of particle components. For example, Krall et al. (2013) and Bell et al. (2014) reported a greater toxicity for elemental (or black) carbon, a large fraction of which is associated with local traffic and domestic heating, whereas Franklin et al. (2008), Beelen et al. (2015) and Dai et al. (2014) found greater effects for sulfur and not elemental carbon.

There is biological support for a role of local traffic particles. Diesel particles have been shown to increase oxidative stress in endothelial cells (Furuyama et al. 2006; Hirano et al. 2003), inducing the production of heme oxygenase-1, a rapid response part of

the body's defense system against oxidative stress (Choi and Alam 1996). The viability of cell cultures of microvascular endothelial cells was also impaired by diesel particles with an accompanying large increase in induction of heme oxygenase-1 (Hirano et al. 2003).

A key gap in the analysis of the acute effects of local air pollution sources has been the lack of studies done in the framework of causal modeling, specifying potential outcomes, and basing their analysis on estimating the difference or ratio of potential outcomes under different exposures. In this paper, we use a causal modeling framework to estimate the causal acute effects of local pollution on daily deaths.

## Methods

### Causal Modeling

To establish causality specification of potential outcomes is required. We designate  $Y_i^A = a$  as the outcome that would occur given an exposure  $A = a$  for the unit  $i$ , and  $Y_i^{A'} = a'$  to be the outcome that would occur if the unit  $i$  were instead exposed to an alternative exposure,  $A = a'$ . Causal modeling seeks to estimate the ratio of the expected value of outcome in the population of subjects  $i$  under the exposure they received versus what it would have been had they received the alternative exposure:  $E(Y_i^A = a)/E(Y_i^{A'} = a')$ . Because only one potential outcome is observed, various methods seek legitimate surrogates for the unobserved potential outcome (Hernán et al. 2008). In this paper, we apply the approach of instrumental variables. An instrumental variable is a variable that is related to outcome only through the exposure of interest.

### Instrumental Variables

Let  $Y_t^A = a$  be the potential outcome (total deaths) in the population of a city exposed to  $A = a$  on day  $t$ , and let  $Y_t^{A'} = a'$  be the potential outcome under the alternative exposure  $a'$ . We would like to estimate  $E(Y_t^A = a)/E(Y_t^{A'} = a')$ , but only  $Y_t^A = a$  is observed. We assume the potential outcome depends on predictors as follows:

$$\text{Log}[E(Y_t^A = a)] = \theta_0 + a\theta_1 + \Phi_t \quad [1]$$

where  $Y_t^A = a$  represents the potential outcome at time  $t$  under exposure  $a$ ,  $\theta_0$  and  $\theta_1$  are the intercept and the slope of exposure, respectively, and  $\Phi_t$  represents all of the other predictors of outcome. Unless we have measured all of the confounders, standard methods, including standard approaches to causal modeling, will give biased estimates of  $\theta_1$ . However, air pollution has many sources of variation. If there is a variable  $Z$  that is one such source of variation in exposure, and  $Z$  is associated with  $Y$  only through  $A$ , then  $Z$  is called

an instrumental variable. Figure 1 shows the directed acyclic graph (DAG) for this scenario. Consequently,  $A_t$  can be expressed as follows:

$$A_t = Z_t\delta + \eta_t \quad [2]$$

where  $\eta_t$  represents the other sources of variation in exposure, and particularly all of the exposure variations that are associated with other measured or unmeasured predictors of outcome. This follows because of the instrument assumption, that  $Z$  is only related to  $Y$  through  $A$ . Formally,  $E(Z|\Phi_t) = 0$  because of the instrument assumption. Then let  $Z1$  and  $Z2$  be equal to  $Z$  such that:

$$E(A|Z1) = a, \text{ and } E(A|Z2) = a'.$$

Consequently,

$$\begin{aligned} \text{Log}[E(Y_t^Z = Z1)] \\ &= E(\theta_0 + \theta_1 a + \Phi_t | Z = Z1) \\ &= \theta_0 + \theta_1 a + E(\Phi_t) \end{aligned} \quad [3]$$

and

$$\begin{aligned} \text{Log}[E(Y_t^Z = Z2)] \\ &= E(\theta_0 + \theta_1 a' + \Phi_t | Z = Z2) \\ &= \theta_0 + \theta_1 a' + E(\Phi_t) \end{aligned} \quad [4]$$

therefore

$$\begin{aligned} \text{Log}[E(Y_t^Z = Z1)] - \text{Log}[E(Y_t^Z = Z2)] \\ &= \theta(a - a'). \end{aligned} \quad [5]$$

As a result, if we use  $Z$  as an instrument for  $A$ , we can recover a causal estimate for  $\theta$ , which is the log rate ratio. Importantly, this is true even if there are unmeasured confounders.

Put less formally, in an observational study the exposure is not randomly assigned, so it may be correlated with other predictors of the outcome. However, air pollution (and other exposures) varies for many reasons. Some of them may be correlated with other predictors of daily deaths. For example, worse-than-average traffic on 1 day will increase both air pollution and stress. However, some sources of variation in air pollution may not be correlated with other predictors of daily deaths. For example, wind speed is unlikely to be correlated with daily stress, smoking, and the like. Hence, if this is true, the fraction of air pollution variation that is produced by wind speed

is randomized with respect to confounders, including unmeasured ones; and if that fraction is associated with daily deaths, the estimated effect should be causal. We discuss this further below.

### Planetary Boundary Layer and Wind Speed as Instruments

The difficulty with instrumental variable analyses is finding a valid instrument that is associated only with outcome through the exposure of interest. Mendelian randomization is an example of an instrumental variable successfully applied in epidemiology, and is justified by knowledge that the biological pathway by which the genotype is associated with exposure is not associated with other predictors of outcome (Holmes et al. 2014). Hence external knowledge is critical to the technique.

The air pollution above a city is a mix of locally emitted pollutants and pollutants transported from elsewhere. The lowest part of the atmosphere, along with its behavior, is influenced by its contact with a planetary surface, which is called planetary boundary layer (PBL) and is characterized by strong vertical mixing (Finlayson-Pitts and Pitts 1986). Above the PBL lies the free atmosphere, which is mostly nonturbulent. The transport of pollutants from the boundary layer to the free atmosphere is slow relative to their vertical mixing within the boundary layer (Seinfeld and Pandis 1998). Therefore, the impact of local emissions on pollutant levels is directly related to the height of the PBL (e.g., for the same local emissions, concentrations of locally emitted pollutants are higher when the boundary layer is low and vice versa) (Seinfeld and Pandis 1998). As a result, the influence of the local emissions is modified by the atmospheric conditions. Over land, the PBL height exhibits a strong diurnal variability, with lower values at night. In addition, the mean PBL height varies substantially from day to day (Seinfeld and Pandis 1998). Besides the vertical transport (influenced by the PBL), locally emitted air pollutants are also transported horizontally, where the influence of local sources increases with decreasing wind speed and vice versa. It is hard to imagine how the PBL height can be directly related to health except through air

**Figure 1.** Directed acyclic graph illustrating an instrumental variable  $Z$ . The association between  $Z$  and  $Y$  is not confounded by  $C$ . By calibrating the instrument to  $A$ , estimates of causal effects of increases in  $A$  can be obtained.

pollution. Similarly, outside of extreme events, wind speed is an unlikely predictor of health other than through air pollution. As such, PBL height and wind speed represent attractive options as instruments for local pollution. However, PBL height and wind speed may vary seasonally and with temperature and other meteorological parameters. We believe that within strata of month and deciles of temperature, further association with predictors of health is unlikely. Hence we looked at local air pollution variation only within month-by-year strata and within deciles of temperature (for the full period), and calibrated that variation with our instruments—that is, we assume short-term predictors of mortality such as smoking, anger, and the like to be uncorrelated with PBL height on a day-to-day level, within month-by-year and decile of temperature. Our analysis took this into account.

A low PBL height and low wind speed are associated with increases in the concentrations of all locally emitted pollutants. Hence, when combined into an instrument, it can tell us that local pollution increases mortality rates (or not), but it will be difficult to identify which pollutants are responsible for the changed mortality rate.

If a single variable is used as an instrument, that variable can obtain the estimated causal effect of exposure on the outcome by regressing the outcome on the instrument, and the instrument on the exposure of interest. The product of those coefficients is the estimated causal effect per unit increase in exposure. Because we have four instrumental variables (PBL and wind speed at lag 0 and lag 1), we regressed the pollution against the four variables first, and used that result (the variation in pollution explained by the four instrumental variables) to generate a single instrumental variable for regression on the outcome. We have chosen to use these variables as instruments for PM<sub>2.5</sub> (particulate matter with aerodynamic diameter  $\leq 2.5$   $\mu\text{m}$ ) as the pollutant most strongly associated with daily deaths. However, this does not demonstrate that the results are attributable exclusively to particles. We evaluated two alternative air pollutant exposures as a sensitivity analysis: black carbon (BC), which represents traffic particles, a large fraction of them locally emitted, and nitrogen dioxide (NO<sub>2</sub>), which is mostly from local combustion.

## Data

### Mortality Data

We analyzed data from the Boston metropolitan area, which includes the following counties: Middlesex, Norfolk, and Suffolk. Mortality data were obtained from the Massachusetts Department of Public Health for the years 2000–2009. The mortality files provided information on the exact date of

death and the underlying cause of death. We chose all-cause non-accidental daily mortality [*International Classification of Diseases, 9th Revision* (ICD-9) codes 0–799] as our outcome to ensure sufficient statistical power.

### Air Quality Data

PM<sub>2.5</sub> and BC measurements were conducted at the Harvard Supersite located on the roof of the Countway Library of the Harvard Medical School near downtown Boston. Ambient BC was measured continuously using an aethalometer (Magee Scientific), and PM<sub>2.5</sub> was measured continuously using a tapered element oscillating microbalance (model 1400a; Rupprecht & Pataschnick Co). Daily averages were computed from the hourly values. We used publicly available daily data on the height of the PBL obtained from the NOAA (National Oceanic and Atmospheric Administration) Reanalysis Data (NOAA 2010). Ambient temperature and wind speed were obtained from the Logan Airport meteorological station.

### Analysis

First we orthogonalized our local air pollution exposures to season and temperature by fitting them to a model with dummy variables for each month of each year, and for each decile of temperature. We used four individual variables to derive one single pollution-calibrated instrumental variable: PBL height and wind speed on the day of death (lag 0) and PBL height and wind speed on the day before death (lag 1). To do this, we used a support vector regression (SVM) (Cortes and Vapnik 1995) with a radial kernel to estimate the remaining variation in PM<sub>2.5</sub> (or in BC or NO<sub>2</sub>) that was explained by those four variables and their products including potential nonlinear dependencies on the predictors. This approach (support vector kernel regression with the radial basis kernel) combines our four instruments into one pollution calibrated instrument, and allows us to compare interquartile range (IQR) changes in the instruments for local pollution computed using each of the pollutants (PM<sub>2.5</sub>, BC, or NO<sub>2</sub>) as an indicator. The kernel regression also incorporates a ridge penalty to shrink the coefficients of the multiple terms to avoid overfitting and collinearity problems. We chose the parameters of the SVM to maximize 10-fold cross-validated  $R^2$ . We used the svm function in the R package *e1071* (version 3.2; R Project for Statistical Computing). We checked the  $R^2$  of the instrument predicting exposure to ensure our instrument was not too weakly associated with exposure to detect an effect. Because previous literature has most commonly used the mean of PM<sub>2.5</sub> on the day of death and the day preceding death as the exposure of interest, we used the mean of the instrumental variable on the day of death and the

day preceding the death as our exposure, and fit a quasi-Poisson regression (allowing for overdispersion) predicting all-cause mortality. We stratified by each month of each year and by deciles of temperature, using indicator variables, and estimated the rate ratio for the instrument.

Boston has lower than average pollution levels for a U.S. city, and there were no violations of the NO<sub>2</sub> annual National Ambient Air Quality (<https://www.epa.gov/criteria-air-pollutants/naaqs-table>) standard of 53 ppb during the study period. There were 19 days which exceeded the new U.S. EPA PM<sub>2.5</sub> daily standard of 35  $\mu\text{g}/\text{m}^3$ . To assure our results apply to low-dose exposures, we repeated the analyses with the instrument excluding days when PM<sub>2.5</sub> exceeded 30  $\mu\text{g}/\text{m}^3$  to ensure that even with measurement error the exposure was below the ambient standard. This excluded 39 days. There are currently no standards for BC.

Granger causality is not a true causal modeling approach, but a heuristic one that argues that omitted covariates that are correlated with time-varying exposure and outcome are as likely to be correlated with tomorrow's exposure as with yesterday's exposure. Hence, if no association is found between future values of exposure and outcome, that suggests there is no omitted confounder. Flanders et al. (2011) give a stronger causal framework using DAGs, and note that the Granger causality approach assumes that, conditional on exposure and all confounders, exposure after the outcome should be uncorrelated with the outcome. However, exposure after the outcome and exposure before the outcome are both associated with the confounders, as illustrated in the DAG in Figure 2. Therefore, in the presence of omitted confounders an association may be expected with the future exposure. Hence, if we fit a model with the past exposure and the future exposure and find an association only with the past exposure, that would argue against such omitted confounders, and vice versa. We tested this approach by rerunning our instrumental variable model with the mean of the instrument (lags 0 and 1) and the

**Figure 2.** Directed acyclic graph for the Granger causality model. Confounder  $U_2$  is measured and controlled, but confounder  $U_1$  is not.  $POL_b$  is pollution before the outcome ( $O$ ), and  $POL_a$  is pollution after the outcome. If  $U_1$  is not controlled, there is a backdoor path from  $O$  to  $POL_a$ , and an association would be expected. Hence, failure to find an association is evidence of a lack of confounding (i.e., no  $U_1$ ).

mean value of the instrument on the second and third days after death. We left 1 day between the exposure before the event and the exposure after the event to produce more stable estimates for each association, given the serial correlation in pollution.

We also conducted a sensitivity analysis to test our assumption that we had a valid instrument. Looking at Figure 1 again, we see that the instrumental variable ( $Z$ ) is associated only with the outcome through the exposure ( $A$ ) (the assumption for instrumental variables). That is, the exposure can be viewed as a mediator of the association of the instrumental variable with the outcome. Then if we control for  $A$ , there should be no association with the instrument any longer (no direct effect) by that assumption. If, in contrast, an association remains, then there is another path from  $Z$  to the outcome, through some confounder. We tested this by fitting a model with both our instrument and the original exposure variable ( $PM_{2.5}$ ).

To put our results in context, we performed a quantitative health impact assessment. Specifically, we estimated the reduction in deaths during the 10 years of study for an IQR reduction in our instrumental variable (after ensuring that such a reduction from the mean would result in an exposure above zero). This was estimated as

$$\text{change in deaths} = \frac{RR - 1}{RR} \text{Total Deaths}$$

where  $RR$  is the rate ratio for the change in exposure,  $\exp(b1 \times \text{IQR})$  where  $b1$  is the coefficient of the instrumental variable, and  $\text{IQR}$  is its interquartile range. This approach is standard in risk assessment (Fann et al. 2011; GBD 2013 Risk Factors Collaborators et al. 2015; U.S. EPA 1999). We computed the total deaths during follow-up (204,386) from our data.

## Results

Table 1 shows descriptive statistics for the variables in our study. Air pollution concentrations were low, and almost always well

**Table 1.** Descriptive statistics of the data: air pollution and daily deaths in Boston, 2000–2009.

Variable	Mean $\pm$ SD	Min	Max
Daily deaths <sup>a</sup>	55.8 $\pm$ 9.5	27	94
$PM_{2.5}$ ( $\mu\text{g}/\text{m}^3$ ) <sup>b</sup>	9.8 $\pm$ 5.8	0.2	67.2
BC ( $\mu\text{g}/\text{m}^3$ ) <sup>b</sup>	0.70 $\pm$ 0.41	0.10	4.70
$\text{NO}_2$ (ppb) <sup>c</sup>	18.4 $\pm$ 6.4	4.0	46.9
PBL (m) <sup>d</sup>	770 $\pm$ 356	110	2,392

below the current U.S. EPA standards (results not shown). Table 2 shows the correlations among the covariates. The correlation between  $PM_{2.5}$  and BC was 0.65, between  $PM_{2.5}$  and  $\text{NO}_2$  was 0.45, and between BC and  $\text{NO}_2$  was 0.57. The correlation between air pollution and the candidate instruments were modest. For example, for  $PM_{2.5}$ , the correlation with PBL height was  $-0.35$ , and with wind speed was  $-0.28$ .

## Instrumental Variable Model

If a model predicting a variable is over fit (e.g., uses too many degrees of freedom), then one would expect the predicted  $R^2$  on left-out monitors to be noticeably smaller than the model  $R^2$  in the training data set. The cross-validated  $R^2$  of the instrumental variable predicting  $PM_{2.5}$  was 0.180, little changed from the  $R^2$  in the training data (0.189). Although low, this is consistent with the fact that most of the  $PM_{2.5}$  in Boston is transported rather than locally emitted, and with PM having other important sources of variation besides PBL and wind speed (Masri et al. 2015). Overfitting was avoided because the tuning parameters of the model calibrating the instrument to  $PM_{2.5}$  were chosen by cross-validation, and because the SVM uses a ridge penalty, where a penalty term is added to the cost function proportional to the sum of the square of the regression coefficients. This penalty constrains the coefficients from varying wildly, or growing too large.

As expected, PBL height and wind speed were better predictors of BC (a large fraction of which is locally emitted) than of  $PM_{2.5}$ . The cross-validated  $R^2$  of the SVM model for BC was 0.36, versus 0.37 without cross-validation. Similarly, the SVM model for  $\text{NO}_2$  had a cross-validated  $R^2$  of 0.39, versus 0.40 without cross-validation.

## Mortality Model

An IQR change in the instrument for local  $PM_{2.5}$  was associated with a 0.90% increase in daily deaths [95% confidence interval (CI): 0.25, 1.56], whereas an IQR change in the instrument for BC was associated with a 0.90% increase in daily deaths (95% CI: 0.08, 1.73). For  $\text{NO}_2$ , an IQR increase in the instrument was associated with a 0.62% increase in daily deaths (95% CI:  $-0.12$ , 1.64). We compared IQR changes for the instrumental variables to

have some basis for comparing effects between the models for  $PM_{2.5}$ , BC, and  $\text{NO}_2$ . When the mortality analysis was restricted to days when  $PM_{2.5}$  was  $< 30 \mu\text{g}/\text{m}^3$  (which excluded 39 days), we found a 0.84% increase in daily deaths for the same increase in the instrument (95% CI: 0.19, 1.50).

When we used the Granger causality approach, the estimated effect of an IQR change in the instrument for  $PM_{2.5}$  remained the same (0.90%; 95% CI: 0.25, 1.96), whereas the forward lagged instrument was not associated with mortality (0.18%; 95% CI:  $-0.45$ , 0.81), suggesting no omitted confounders. Although the power for a Granger causality test may not be strong, the much smaller effect size as well as lack of significance both indicate a lack of confounding.

Finally, when we added the mean of  $PM_{2.5}$  on lags 0 and 1 to the model in addition to the instrumental variable, the instrumental variable was far from significant ( $p > 0.29$ ) while the  $PM_{2.5}$  variable was significant. This indicates that there was no path from instrument to the outcome except through  $PM_{2.5}$ , and hence that the instrumental variable assumption was valid.

## Discussion

Using a framework based on potential outcomes, we have estimated the causal effect of an IQR increase in local air pollution on daily deaths in Boston. The increase in deaths for an IQR increase in the instrument for exposure was about 0.90% using either particle measure to calibrate the instrument; for  $\text{NO}_2$  it was lower (0.62%) with confidence intervals that crossed zero. Using the approach of Granger causality, we saw no change in the estimated effect of our instrument when controlling for exposure on future days and the association with future exposure was close to zero and far from significant. Further, the association persisted when restricted to days well below the recently tightened U.S. EPA 24-hr standard for  $PM_{2.5}$  ( $35 \mu\text{g}/\text{m}^3$ ), and in a city that never violated the hourly  $\text{NO}_2$  National Ambient Air Quality standard during the study period. Hence, these effects are evident at levels below currently permissible limits.

A key advantage of the instrumental variable approach is that it provides protection against unmeasured confounders. We have approached this in three ways. First, we

**Table 2.** Correlation matrix of the exposures.

	$PM_{2.5}$ ( $\mu\text{g}/\text{m}^3$ )	BC ( $\mu\text{g}/\text{m}^3$ )	$\text{NO}_2$ (ppb)	PBL (m)	Temperature ( $^{\circ}\text{C}$ )	Wind speed (knots)
$PM_{2.5}$ ( $\mu\text{g}/\text{m}^3$ )	1					
BC ( $\mu\text{g}/\text{m}^3$ )	0.65	1				
$\text{NO}_2$ (ppb)	0.45	0.57	1			
PBL (m)	$-0.35$	$-0.52$	$-0.35$	1		
Temperature ( $^{\circ}\text{C}$ )	0.30	0.26	$-0.25$	$-0.23$	1	
Wind speed (knots)	$-0.28$	$-0.52$	$-0.37$	0.54	$-0.28$	1

have shown that if we have a valid instrument, then the association will be causal even in the presence of unmeasured confounders. We focused on the variation in local pollution within deciles of temperature and also stratified on each month of each year. We then chose as instruments variables (PBL height and wind speed) we believed, based on external knowledge, are unlikely to be associated with mortality except through air pollution. Second, we have confirmed that values of the instrument following the day of death are not significantly associated ( $p = 0.57$ ) with daily deaths, and that control for them did not change the estimated effect of the instrument. This assures that omitted confounders with the same broad temporal variability are not confounding our instrument. And third, we have tested the instrument assumption (that the association of the instrument is only through air pollution) by controlling for air pollution, and showing that no significant association with the instrument remained ( $p > 0.29$ ). We believe that this makes a strong case for a causal effect.

Support for this causal interpretation also comes from an extensive toxicological and human exposure literature on some of these local pollutants. For example, Furuyama et al. (2006) found increased oxidative stress in endothelial cells exposed to diesel exhaust, and in humans Rossner et al. (2007) reported increased levels of F-2 isoprostane and 8-OHdG (8-hydroxy-2'-deoxyguanosine) in bus drivers compared with controls. The human study contrasted urinary 8-OHdG in 50 bus drivers and 50 controls measured in three successive seasons in Prague. In logistic regression analysis,  $PM_{2.5}$ , but not volatile organic compound or polycyclic aromatic hydrocarbon exposure, was associated with 8-OHdG. Romieu et al. (2008) measured malondialdehyde in exhaled breath condensate at 480 visits in a panel of 108 children with asthma seen every 2 weeks, and found it was positively associated with  $PM_{2.5}$  at the nearest monitoring station within 5 km of their home and school.

Increased atherosclerosis has also been reported in animals with long-term exposure to particles, much of which was from traffic (Sun et al. 2005, 2008). Another study (Soares et al. 2009) placed hyperlipemic mice in two exposure chambers 20 m from a road. One chamber was filtered to remove particles and the other was not. After 120 days of exposure they documented increased oxidation of low-density lipoprotein, increased thickness of the arterial wall, and greater plaque growth and instability (Soares et al. 2009). Along with the increased oxidative stress, atherosclerosis, and plaque instability, increased thrombosis has also been associated with local pollution. Nemmar et al. (2002, 2003) found

that both diesel and ultrafine particles were associated with increased thrombosis in an animal model, and Carlsten et al. (2007, 2008) found that controlled exposure to diesel exhaust increased coagulation markers and thrombosis in human volunteers. Ischemia has likewise been produced experimentally by diesel exposure in a double-blind randomized crossover exposure of 20 people with previous myocardial infarction to 1 hr of dilute diesel exhaust or filtered air (Mills et al. 2007).

An intervention trial in Beijing had 15 young adults (median age, 28 years) walk the streets for 2 hr twice, once wearing a particle-filtering mask, and once without a mask. Blood pressure was measured continuously during the two 2-hr walks and was 7 mmHg lower when wearing the mask (Langrish et al. 2009). These results, combined with the instrumental variable approach and Granger causality model, support a causal interpretation.

The weaker association of the instrumental variables when calibrated to  $NO_2$  than to particles suggests that local particles may be more important in this relationship, but no definite conclusions can be drawn.

To put this result in context, the mean  $PM_{2.5}$ ,  $NO_2$ , and BC ( $9.8 \mu g/m^3$ , 18.4 ppb, and  $0.7 \mu g/m^3$ ) were all greater than their IQRs ( $6.32 \mu g/m^3$ , 8.4 ppb, and  $0.50 \mu g/m^3$ , respectively), indicating that IQR changes in the pollutant concentrations would result in levels above zero, and hence are plausible. Computing the attributable risk for an IQR change in exposure to the instrument, we estimated that local air pollution was responsible for 1,826 deaths in the Boston metropolitan area during the study period. This is a substantial public health burden.

Local air pollution in Boston has multiple sources, including traffic, combustion of fuel oil and residual oil for heating, and wood burning (Masri et al. 2015). Traffic pollution has fallen because of reduced U.S. EPA emission standards on vehicles, low-sulfur diesel oil requirements, the retrofit of particle filters onto buses, and the introduction of compressed natural gas buses for part of the fleet (Masri et al. 2015; U.S. EPA 2012). Continuing retirement of older vehicles will likely continue this trend. Wood burning, on the other hand has increased and now accounts for 19% of particles in Boston (Masri et al. 2015), and though the U.S. EPA has proposed new emission standards for future stoves and furnaces, there is no retrofit requirement. Heating oil, while similar to diesel oil, is still allowed much higher sulfur content. Hence, there are opportunities for local action to reduce this public health burden.

There are several limitations to our study. First, we have assumed we have a valid instrument. Although we have good evidence that

this is the case, one can never guarantee it. It is possible that behavior is modified on low-PBL or low-wind speed days in a way that affects mortality risk. A second limitation is that we have provided our proof that an instrumental variable protects against unmeasured confounding in the context of a log-linear model between mortality and air pollution, and assume that model is correct. This is the traditional approach for daily death counts, but we cannot be sure it is correct. In addition, all-cause mortality includes some causes of death unlikely to be associated with air pollution. This decreases power in our analysis, but still leaves us with a valid estimate of the impact on all deaths. The air pollutants, PBL, and wind speed were measured at only one location, which may introduce some error into the instrumental variable, which, if the instrument assumption is valid, should result in an underestimate of risk. Power is always an issue, and the power for a Poisson regression depends on the total number of events. In our case, there were 204,386 deaths during the study period, which indicates good power for our hypothesis tests.

In summary, we have used causal methods to estimate the acute effect of local air pollution on daily deaths, and found that concentrations below current limits are associated with important increases in daily deaths. If, when stratified by month and temperature, our instrument is independent of other causes of mortality, this association is causal, an interpretation supported by toxicological studies.

# Association of Short-term Exposure to Air Pollution With Mortality in Older Adults

Qian Di, MS; Lingzhen Dai, ScD; Yun Wang, PhD; Antonella Zanobetti, PhD; Christine Choirat, PhD; Joel D. Schwartz, PhD; Francesca Dominici, PhD

**IMPORTANCE** The US Environmental Protection Agency is required to reexamine its National Ambient Air Quality Standards (NAAQS) every 5 years, but evidence of mortality risk is lacking at air pollution levels below the current daily NAAQS in unmonitored areas and for sensitive subgroups.

**OBJECTIVE** To estimate the association between short-term exposures to ambient fine particulate matter (PM<sub>2.5</sub>) and ozone, and at levels below the current daily NAAQS, and mortality in the continental United States.

**DESIGN, SETTING, AND PARTICIPANTS** Case-crossover design and conditional logistic regression to estimate the association between short-term exposures to PM<sub>2.5</sub> and ozone (mean of daily exposure on the same day of death and 1 day prior) and mortality in 2-pollutant models. The study included the entire Medicare population from January 1, 2000, to December 31, 2012, residing in 39 182 zip codes.

**EXPOSURES** Daily PM<sub>2.5</sub> and ozone levels in a 1-km × 1-km grid were estimated using published and validated air pollution prediction models based on land use, chemical transport modeling, and satellite remote sensing data. From these gridded exposures, daily exposures were calculated for every zip code in the United States. Warm-season ozone was defined as ozone levels for the months April to September of each year.

**MAIN OUTCOMES AND MEASURES** All-cause mortality in the entire Medicare population from 2000 to 2012.

**RESULTS** During the study period, there were 22 433 862 million case days and 76 143 209 control days. Of all case and control days, 93.6% had PM<sub>2.5</sub> levels below 25 µg/m<sup>3</sup>, during which 95.2% of deaths occurred (21 353 817 of 22 433 862), and 91.1% of days had ozone levels below 60 parts per billion, during which 93.4% of deaths occurred (20 955 387 of 22 433 862). The baseline daily mortality rates were 137.33 and 129.44 (per 1 million persons at risk per day) for the entire year and for the warm season, respectively. Each short-term increase of 10 µg/m<sup>3</sup> in PM<sub>2.5</sub> (adjusted by ozone) and 10 parts per billion (10<sup>-9</sup>) in warm-season ozone (adjusted by PM<sub>2.5</sub>) were statistically significantly associated with a relative increase of 1.05% (95% CI, 0.95%-1.15%) and 0.51% (95% CI, 0.41%-0.61%) in daily mortality rate, respectively. Absolute risk differences in daily mortality rate were 1.42 (95% CI, 1.29-1.56) and 0.66 (95% CI, 0.53-0.78) per 1 million persons at risk per day. There was no evidence of a threshold in the exposure-response relationship.

**CONCLUSIONS AND RELEVANCE** In the US Medicare population from 2000 to 2012, short-term exposures to PM<sub>2.5</sub> and warm-season ozone were significantly associated with increased risk of mortality. This risk occurred at levels below current national air quality standards, suggesting that these standards may need to be reevaluated.

In the United States, the Clean Air Act<sup>1</sup> requires a review of National Ambient Air Quality Standards (NAAQS) for fine particulate matter (PM<sub>2.5</sub>) and ozone every 5 years.<sup>2</sup> In 2012, the annual and 24-hour NAAQS for PM<sub>2.5</sub> were set to 12 µg/m<sup>3</sup> and 35 µg/m<sup>3</sup>, respectively. With no annual standard for ozone, the 8-hour NAAQS for ozone was set to 70 parts per billion (ppb). Currently, the review of these standards is ongoing, with public comments expected in the fall of 2017.<sup>3</sup>

Several studies have provided evidence that short-term exposures to PM<sub>2.5</sub> and ozone were associated with mortality,<sup>4-8</sup> but these studies primarily included large and well-monitored metropolitan areas. While the US Environmental Protection Agency (EPA) is considering more stringent NAAQS, evidence is needed to clarify the association between mortality risk and exposure levels below the daily NAAQS and in rural and unmonitored areas.

The Clean Air Act<sup>1</sup> also requires the US EPA to set standards to protect “sensitive subgroups.” To estimate the health risk of short-term exposure to air pollution for specific subgroups (eg, underrepresented minorities and those with low socioeconomic status, such as persons eligible for Medicaid), a large population is necessary to achieve maximum accuracy and adequate statistical power.

A case-crossover study was conducted to examine all deaths of Medicare participants in the continental United States from 2000 throughout 2012 and estimate the mortality risk associated with short-term exposures to PM<sub>2.5</sub> and ozone in the general population as well as in subgroups. The study was designed to estimate the association between daily mortality and air pollution at levels below current daily NAAQS to evaluate the adequacy of the current air quality standards for PM<sub>2.5</sub> and ozone.

## Methods

This study was approved by the institutional review board at the Harvard T.H. Chan School of Public Health. As a study of previously collected administrative data, it was exempt from informed consent requirements.

### Study Population

Using claims data from the Centers for Medicare & Medicaid Services, all deaths among all Medicare beneficiaries were identified during the period 2000 to 2012, providing enough power to analyze the risk of mortality associated with PM<sub>2.5</sub> and ozone concentrations much lower than the current standards (Table 1). For each beneficiary, information was extracted on the date of death, age, sex, race, ethnicity, zip code of residence, and eligibility for Medicaid (a proxy for low income) to assess the associations of mortality with PM<sub>2.5</sub> and ozone concentrations in potentially vulnerable subgroups. Self-reported information on race and ethnicity was obtained from Medicare beneficiary files.

### Outcome

The study outcome was all-cause mortality. Individuals with a verified date of death between January 1, 2000, and

## Key Points

**Question** What is the association between short-term exposure to air pollution below current air quality standards and all-cause mortality?

**Finding** In a case-crossover study of more than 22 million deaths, each 10-µg/m<sup>3</sup> daily increase in fine particulate matter and 10-parts-per-billion daily increase in warm-season ozone exposures were associated with a statistically significant increase of 1.42 and 0.66 deaths per 1 million persons at risk per day, respectively.

**Meaning** Day-to-day changes in fine particulate matter and ozone exposures were significantly associated with higher risk of all-cause mortality at levels below current air quality standards, suggesting that those standards may need to be reevaluated.

December 31, 2012, were included. Individuals with an unverified date of death, or still living after December 31, 2012, were excluded.

### Study Design

We estimated the association between short-term exposure to PM<sub>2.5</sub> (adjusted by ozone) and short-term exposure to ozone (adjusted by PM<sub>2.5</sub>) and all-cause mortality using a case-crossover design.<sup>9</sup> Specifically, “case day” was defined as the date of death. For the same person, we compared daily air pollution exposure on the case day vs daily air pollution exposure on “control days.” Control days were chosen (1) on the same day of the week as the case day to control for potential confounding effect by day of week; (2) before and after the case day (bidirectional sampling) to control for time trend<sup>10,11</sup>; and (3) only in the same month as the case day to control for seasonal and subseasonal patterns.<sup>10,12</sup> Individual-level covariates and zip code-level covariates that did not vary day to day (eg, age, sex, race/ethnicity, socioeconomic status, smoking, and other behavioral risk factors) were not considered to be confounders as they remain constant when comparing case days vs control days.

### Environmental Data

Daily ambient levels of PM<sub>2.5</sub> and ozone were estimated from published and validated air pollution prediction models.<sup>13,14</sup> Combining monitoring data from the EPA, satellite-based measurements, and other data sets, neural networks were used to predict 24-hour PM<sub>2.5</sub> and 8-hour maximum ozone concentrations at each 1-km × 1-km grid in the continental United States, including locations with no monitoring sites. Cross-validation indicated good agreement between predicted values and monitoring values ( $R^2 = 0.84$  for PM<sub>2.5</sub> and  $R^2 = 0.76$  for ozone) and at low concentrations ( $R^2 = 0.85$  when constraining to 24-hour PM<sub>2.5</sub> <25 µg/m<sup>3</sup> and  $R^2 = 0.75$  when constraining to daily 8-hour maximum ozone <60 ppb). Details have been published elsewhere.<sup>13,14</sup> Warm season was defined to be from April 1 to September 30, which is the specific time window to examine the association between ozone and mortality.

Meteorological variables, including air and dew point temperatures, were retrieved from North American Regional Reanalysis data and estimated daily mean values were determined for each 32-km × 32-km grid in the continental United States.<sup>15</sup>

For each case day (date of death) and its control days, the daily 24-hour PM<sub>2.5</sub>, 8-hour maximum ozone, and daily air and dew point temperatures were assigned based on zip code of residence of the individual (eAppendix 1 in the [Supplement](#)). Because we estimated air pollution levels everywhere in the

continental United States, the number of zip codes included in this study was 39 182, resulting in a 33% increase compared with the number of zip codes with a centroid less than 50 km from a monitor (n = 26 115).

### Statistical Analysis

The relative risk (RR) of all-cause mortality associated with short-term exposures to PM<sub>2.5</sub> (adjusted by ozone) and warm-season ozone (adjusted by PM<sub>2.5</sub>) was estimated by fitting a conditional logistic regression to all pairs of case days and matched control days (eAppendix 2 in the [Supplement](#)).<sup>9</sup> The regression model included both pollutants as main effects and natural splines of air and dew point temperatures with 3 *df* to control for potential residual confounding by weather. For each case day, daily exposure to air pollution was defined as the mean of the same day of death (lag 0-day) and 1 day prior (lag 1-day), denoted as lag 01-day.<sup>5,16,17</sup> Relative risk increase (RRI) was defined as  $RR - 1$ . The absolute risk difference (ARD) of all-cause mortality associated with air pollution was defined as  $ARD = \alpha \times (RR - 1)/RR$ , where  $\alpha$  denotes the baseline daily mortality rate (eAppendix 3 in the [Supplement](#)).

The robustness of the analysis results was assessed with respect to (1) choosing the *df* used for the confounding adjustment for temperature, (2) using lag 01-day exposure as the exposure metric, (3) the definition of warm season, and (4) using only air pollution measurements from the nearest EPA monitoring sites. Splines on meteorological variables with 6 and 9 *df* yielded results with a difference of less than 5% of the standard error (eFigure 1 in the [Supplement](#)). The main analysis, which used the lag 01-day exposure, yielded the lowest values of the Akaike Information Criteria values, indicating better fit to the data (eTable in the [Supplement](#)). Different definitions of warm season yielded similar risk estimates (eAppendix 4 in the [Supplement](#)), and using exposure mea-

Table 1. Baseline Characteristics of Study Population (2000-2012)

Baseline Characteristic	Value
Case days, No.	22 433 862
Control days, No.	76 143 209
Among All Cases (n = 22 433 862), %

Eligible	22.64

Table 2. Relative Risk Increase and Absolute Risk Difference of Daily Mortality Associated With Each 10-μg/m<sup>3</sup> Increase in PM<sub>2.5</sub> and Each 10-ppb Increase in Ozone

Air Pollutant Analysis	Relative Risk Increase, % (95% CI)		Absolute Risk Difference in Daily Mortality Rates, No. per 1 Million Persons at Risk per Day (95% CI) <sup>a</sup>	
	PM <sub>2.5</sub>	Ozone <sup>b</sup>	PM <sub>2.5</sub>	Ozone <sup>b</sup>
Main analysis <sup>c</sup>	1.05 (0.95-1.15)	0.51 (0.41-0.61)	1.42 (1.29-1.56)	0.66 (0.53-0.78)
Low-exposure analysis <sup>d</sup>	1.61 (1.48-1.74)	0.58 (0.46-0.70)	2.17 (2.00-2.34)	0.74 (0.59-0.90)
Single-pollutant analysis <sup>e</sup>	1.18 (1.09-1.28)	0.55 (0.48-0.62)	1.61 (1.48-1.73)	0.71 (0.62-0.79)
Nearest monitors analysis <sup>f</sup>	0.83 (0.73-0.93)	0.35 (0.28-0.41)	1.13 (0.99-1.26)	0.45 (0.37-0.53)

Abbreviations: PM<sub>2.5</sub>, fine particulate matter; ppb, parts per billion.

<sup>a</sup> The daily baseline mortality rate was 137.33 per 1 million persons at risk per day; the warm-season daily baseline mortality rate was 129.44 per 1 million persons at risk per day.

<sup>b</sup> Ozone analyses included days from the warm season only (April 1 to September 30).

<sup>c</sup> The main analysis used the mean of daily exposure on the same day of death and 1 day prior (lag 01-day) as the exposure metric for both PM<sub>2.5</sub> and ozone, and controlled for natural splines of air and dew point temperatures with 3 *df*. The main analysis considered the 2 pollutants jointly included into the regression model and estimated the percentage increase in the daily mortality rate associated with a 10-μg/m<sup>3</sup> increase in PM<sub>2.5</sub> exposure adjusted for ozone and the percentage increase in daily mortality rate associated with a 10-ppb increase in warm-season ozone exposure adjusted for PM<sub>2.5</sub>.

<sup>d</sup> The low-exposure analysis had the same model specifications as the 2-pollutant analysis and was constrained for days when PM<sub>2.5</sub> was below 25 μg/m<sup>3</sup> or ozone below 60 ppb.

<sup>e</sup> The single-pollutant analysis estimated the percentage increase in the daily mortality rate associated with a 10-μg/m<sup>3</sup> increase in PM<sub>2.5</sub> exposure without adjusting for ozone and the percentage increase in the daily mortality rate associated with a 10-ppb increase in ozone exposure without adjusting for PM<sub>2.5</sub>.

<sup>f</sup> PM<sub>2.5</sub> and ozone monitoring data were retrieved from the US Environmental Protection Agency Air Quality System, which provides the daily mean of PM<sub>2.5</sub> and daily 8-hour maximum ozone levels at each monitoring site. Daily ozone concentrations were averaged from April 1 to September 30. Individuals were assigned to the PM<sub>2.5</sub> and ozone levels from the nearest monitor site within 50 km. Those living 50 km from any monitoring site were excluded.

surements from the nearest monitors resulted in attenuated, but still significant, risk estimates (Table 2).

The subgroup analyses were conducted by sex (male and female), race/ethnicity (white, nonwhite, and others), age ( $\leq 69$ , 70-74, 75-84, and  $\geq 85$  years), eligibility for Medicaid, and population density (quartiles). We fitted separate conditional logistic regressions to the data for each subgroup and obtained subgroup-specific estimates of RR and ARD. We implemented a 2-sample test for assessing statistically significant differences in the estimated RR and ARD between categories within each subgroup (eg, female vs male), based on the point estimate and standard error (se) (Appendix 5 in the Supplement):

$$Z = \frac{RR_{\text{male}} - RR_{\text{female}}}{\sqrt{se(RR_{\text{male}})^2 + se(RR_{\text{female}})^2}}$$

The goal was to estimate mortality rate increases (both RRI and ARD) at air pollution levels well below the current daily NAAQS. The analysis was restricted to days with daily air pollution concentrations below 25  $\mu\text{g}/\text{m}^3$  for  $\text{PM}_{2.5}$  and 60 ppb for ozone. We chose 25  $\mu\text{g}/\text{m}^3$  and 60 ppb instead of the current daily NAAQS (35  $\mu\text{g}/\text{m}^3$  for daily  $\text{PM}_{2.5}$  and 70 ppb for 8-hour maximum ozone) because levels of  $\text{PM}_{2.5}$  and ozone on most of the days included in the analysis were already below the current safety standards.

Exposure-response curves were estimated between  $\text{PM}_{2.5}$  or ozone and mortality by replacing linear terms for the 2 pollutants with penalized splines for both  $\text{PM}_{2.5}$  and ozone.

All analyses were performed in R software version 3.3.2 (R Foundation). Computations were run on (1) the Odyssey cluster supported by the Faculty of Arts and Sciences Division of Science, Research Computing Group at Harvard University and (2) the Research Computing Environment supported by the Institute for Quantitative Social Science in the Faculty of Arts and Sciences at Harvard University.

## Results

During the study period, there were more than 22 million case days (deaths) and more than 76 million control days (Table 1). Of all case and control days, 93.6% had  $\text{PM}_{2.5}$  levels below 25  $\mu\text{g}/\text{m}^3$ , during which 95.2% of deaths occurred (21 353 817 of 22 433 862), and 91.1% of days had ozone levels below 60 ppb, during which 93.4% of deaths occurred (20 955 387 of 22 433 862). The baseline daily mortality rates were 137.33 and 129.44 (per 1 million persons at risk per day [per 1M per day]) for the entire year and for the warm season, respectively. The mean time between case and control days was 12.55 days (range 7-28 days), with minimal differences in air and dew point temperatures between case and control days (0.003°C and 0.01°C, respectively). During the study period, the mean concentrations of  $\text{PM}_{2.5}$  and ozone were 11.6  $\mu\text{g}/\text{m}^3$  and 37.8 ppb, respectively. Figure 1 and Figure 2 show the daily  $\text{PM}_{2.5}$  and ozone time series by state, respectively.

Each 10- $\mu\text{g}/\text{m}^3$  and 10-ppb increase in the lag 01-day exposure for  $\text{PM}_{2.5}$  and warm-season ozone was associated with

an RRI of 1.05% (95% CI, 0.95%-1.15%) and 0.51% (95% CI, 0.41%-0.61%) in the daily mortality rate. The ARDs were 1.42 (95% CI, 1.29-1.56) and 0.66 (95% CI, 0.53-0.78) per 1M per day. These associations remained significant when examining days below 25  $\mu\text{g}/\text{m}^3$  for  $\text{PM}_{2.5}$  and below 60 ppb for ozone, with larger effect size estimates for both  $\text{PM}_{2.5}$  and ozone (RRI: 1.61% [95% CI, 1.48%-1.74%] and 0.58% [95% CI, 0.46%-0.70%]; ARD: 2.17 [95% CI, 2.00-2.34] and 0.74 [95% CI, 0.59-0.90] per 1M per day, respectively) (Table 2).  $\text{PM}_{2.5}$  was associated with higher mortality rate in some subgroups, including Medicaid-eligible individuals (RRI: 1.49% [95% CI, 1.29%-1.70%]; ARD: 3.59 [95% CI, 3.11-4.08] per 1M per day; interaction:  $P < .001$ ), individuals older than 70 years (eg, for  $\geq 85$  years, RRI: 1.38% [95% CI, 1.23%-1.54%]; ARD: 5.35 [95% CI, 4.75-5.95] per 1M per day; interaction:  $P < .001$ ), and females (RRI: 1.20% [95% CI, 1.07%-1.33%]; ARD: 1.56 [95% CI, 1.39-1.72] per 1M per day; interaction:  $P = .02$ ) (Figure 3 and Figure 4). The effect estimates for  $\text{PM}_{2.5}$  increased with age. The effect estimate for black individuals was higher than that for white individuals ( $P = .001$ ; eFigure 2 in the Supplement). For ozone, similar patterns were observed, but with less contrast between groups. No significant differences were found in the short-term associations between air pollution exposure ( $\text{PM}_{2.5}$  and ozone) and mortality across areas with different population density levels (Figure 3 and Figure 4). Effect estimates using different lags of exposure are shown in eFigure 3 in the Supplement.

Figure 5 shows the estimated exposure-response curves for  $\text{PM}_{2.5}$  and ozone. The slope was steeper at  $\text{PM}_{2.5}$  levels below 25  $\mu\text{g}/\text{m}^3$  ( $P < .001$ ), consistent with the low-exposure analysis (Table 2). Both  $\text{PM}_{2.5}$  and ozone exposure-responses were almost linear, with no indication of a mortality risk threshold at very low concentrations. eFigure 4 in the Supplement shows the exposure-response curves for  $\text{PM}_{2.5}$  when restricted to just the warm season and for ozone when not restricted to the warm season; results were similar.

## Discussion

In this large case-crossover study of all Medicare deaths in the continental United States from 2000 to 2012, a 10- $\mu\text{g}/\text{m}^3$  daily increase in  $\text{PM}_{2.5}$  and a 10-ppb daily increase in warm-season ozone exposures were associated with a statistically significant increase of 1.42 and 0.66 deaths per 1M per day, respectively. The risk of mortality remained statistically significant when restricting the analysis to days with  $\text{PM}_{2.5}$  and ozone levels much lower than the current daily NAAQS.<sup>18</sup> This study included individuals living in smaller cities, towns, and rural areas that were unmonitored and thus excluded from previous time series studies. There were no significant differences in the mortality risk associated with air pollution among individuals living in urban vs rural areas. Taken together, these results provide evidence that short-term exposures to  $\text{PM}_{2.5}$  and ozone, even at levels much lower than the current daily standards, are associated with increased mortality, particularly for susceptible populations.

Figure 1. Daily Mean  $PM_{2.5}$  Concentrations in the Continental United States, 2000-2012

Daily mean fine particulate matter ( $PM_{2.5}$ ) concentrations were calculated and plotted by state. The time-series plot at the bottom indicates the national daily mean values across all locations. Boxplots show the distribution of daily  $PM_{2.5}$  levels for each state. The blue dashed line indicates the daily National Ambient Air Quality Standards (NAAQS) for  $PM_{2.5}$  (35  $\mu g/m^3$ ). The line across the box,

upper hinge, and lower hinge represent the median value, 75th percentile (Q3), and 25th percentile (Q1), respectively. The upper whisker is located at the smaller of the maximal value and  $Q3 + 1.5 \times$  interquartile range; the lower whisker is located at the larger of the minimal value and  $Q1 - 1.5 \times$  interquartile range. Any values that lie beyond the upper and lower whiskers are outliers.

Figure 2. Daily 8-Hour Maximum Ozone Concentrations in the Continental United States, 2000-2012

Daily mean 8-hour maximum ozone concentrations were calculated and plotted by state. The time-series plot at the bottom indicates the national daily mean values across all locations. Boxplots show the distribution of daily ozone levels for each state. The blue dashed line indicates the daily National Ambient Air Quality Standards (NAAQS) for ozone (70 parts per billion [ppb]). The line across the box, upper hinge, and lower hinge represent the median value,

75th percentile (Q3), and 25th percentile (Q1), respectively. The upper whisker is located at the smaller of the maximal value and  $Q3 + 1.5 \times$  interquartile range; the lower whisker is located at the larger of the minimal value and  $Q1 - 1.5 \times$  interquartile range. Any values that lie beyond the upper and lower whiskers are outliers.

Figure 3. Relative Risk Increase and Absolute Risk Difference of Daily Mortality Associated With 10- $\mu\text{g}/\text{m}^3$  Increase in Fine Particulate Matter ( $\text{PM}_{2.5}$ )

For the main analysis, subgroup analyses used a 2-pollutant analysis (with both  $\text{PM}_{2.5}$  and ozone), based on the mean of daily exposure on the same day of death and 1 day prior (lag 01-day) as the exposure metric for  $\text{PM}_{2.5}$ , and controlled for natural splines of air and dew point temperatures (each with 3 df). Vertical lines indicate effects for the entire study population. Subgroup analyses were conducted for each subgroup (eg, male or female, white or nonwhite, Medicare eligible or Medicare ineligible, age groups, and quartiles of population density). For the main analysis and each subgroup, conditional logistic

regressions were run to obtain relative risk increases and calculated absolute risk difference based on baseline mortality rates (eAppendix 2 in the Supplement). Numbers in the figure represent point estimates, 95% CIs, and P values for effect modifications. The reference groups were used when assessing effect modification.

<sup>a</sup> Statistically significant effect estimate (at 5% level) compared with the reference group.

The Clean Air Act<sup>1</sup> requires the administrator of the US EPA to set NAAQS at levels that provide “protection for at-risk populations, with an adequate margin of safety.”<sup>19</sup> In this study, Medicaid-eligible individuals, females, and elderly individuals had higher mortality rate increases associated with  $\text{PM}_{2.5}$

than other groups. Previous studies have found similar results in some subgroups.<sup>20,21</sup> Poverty, unhealthy lifestyle, poor access to health care, and other factors may make some subgroups more vulnerable to air pollution. The exact mechanism is worth exploring in future studies.

Figure 4. Relative Risk Increase and Absolute Risk Difference of Daily Mortality Associated With 10-Parts-per-Billion (ppb) Increase in Ozone

For the main analysis, subgroup analyses used a 2-pollutant analysis (with both  $PM_{2.5}$  and ozone), based on the mean of daily exposure on the same day of death and 1 day prior (lag 01-day) as the exposure metric for ozone, and controlled for natural splines of air and dew point temperatures (each with 3 *df*). Vertical lines indicate effects for the entire study population. Subgroup analyses were conducted for each subgroup (eg, male or female, white or nonwhite, Medicare eligible or Medicare ineligible, age groups, and quartiles of population density). For the main analysis and each subgroup, conditional logistic regressions were run to obtain relative risk increases, and calculated absolute

risk difference based on baseline mortality rates (eAppendix 2 in the Supplement). For ozone, analyses were restricted to the warm season (April to September). Numbers in the figure represent point estimates, 95% CIs, and P values for effect modifications. The reference groups were used when assessing effect modification.

<sup>a</sup> Statistically significant effect estimate (at 5% level) compared with the reference group.

The current NAAQS for daily  $PM_{2.5}$  is 35  $\mu g/m^3$ . When restricting the analysis to daily  $PM_{2.5}$  levels below 25  $\mu g/m^3$ , the association between short-term  $PM_{2.5}$  exposure and mortality remained but was elevated. The current daily

NAAQS for ozone is 70 ppb; when restricting the analysis to daily warm-season ozone concentrations below 60 ppb, the effect size also increased slightly. The exposure-response curves revealed a similar pattern. These results indicate

Figure 5. Estimated Exposure-Response Curves for Short-term Exposures to Fine Particulate Matter (PM<sub>2.5</sub>) and Ozone

A 2-pollutant analysis with separate penalized splines on PM<sub>2.5</sub> (A) and ozone (B) was conducted to assess the percentage increase in daily mortality at various pollution levels. Dashed lines indicate 95% CIs. The mean of daily

exposure on the same day of death and 1 day prior (lag 01-day) was used as metrics of exposure to PM<sub>2.5</sub> and ozone. Analysis for ozone was restricted to the warm season (April to September). Ppb indicates parts per billion.

that air pollution is associated with an increase in daily mortality rates, even at levels well below the current standards.

The exposure-response relationship between PM<sub>2.5</sub> exposure and mortality was consistent with findings of previous studies. One study combined exposure-response curves from 22 European cities and reported an almost linear relationship between PM<sub>2.5</sub> and mortality.<sup>22</sup> Another multicity study reported a linear relationship down to 2-µg/m<sup>3</sup> PM<sub>2.5</sub>.<sup>23</sup> The present study found a similarly linear exposure-response relationship below 15-µg/m<sup>3</sup> PM<sub>2.5</sub> and a less steep slope above this level.

For ozone, the linear exposure-response curve with no threshold described in this study is consistent with earlier research. An almost linear exposure-response curve for ozone was previously reported with no threshold or a threshold at very low concentrations.<sup>24</sup> A study from the Netherlands also concluded that if an ozone threshold exists, it does so at very low levels.<sup>25</sup>

Findings from this study are also consistent with the literature regarding the observed effect sizes of both PM<sub>2.5</sub><sup>5,8,16,26-28</sup> and ozone.<sup>7,20,29,30</sup> This study further demonstrates that in more recent years, during which air pollution concentrations have fallen, statistically significant associations between mortality and exposures to PM<sub>2.5</sub> and ozone persisted.

The association of mortality and PM<sub>2.5</sub> exposure is supported by a large number of published experimental studies in animals<sup>31-33</sup> and in humans exposed to traffic air pollution,<sup>34,35</sup> diesel particles,<sup>36</sup> and unfiltered urban air.<sup>37</sup> Similarly, a review of toxicological studies and a recent panel study found that ozone exposure was associated with multiple adverse health outcomes.<sup>38,39</sup>

### Strengths

This study has several strengths. First, to our knowledge, this is the largest analysis of daily air pollution exposure

and mortality to date, with approximately 4 times the number of deaths included in a previous large study.<sup>5</sup> Second, this study assessed daily exposures using air pollution prediction models that provide accurate estimates of daily levels of PM<sub>2.5</sub> and ozone for most of the United States, including previously unmonitored areas. An analysis that relied only on exposure data from monitoring stations was found to result in a downward bias in estimates (Table 2). Third, the inclusion of more than 22 million deaths from 2000 to 2012 from the entire Medicare population provided large statistical power to detect differences in mortality rates in potentially vulnerable populations and to estimate mortality rates at very low PM<sub>2.5</sub> and ozone concentrations. Fourth, this study estimated the air pollution-mortality association well below the current daily NAAQS and in unmonitored areas, and it did not identify significant differences in the mortality rate increase between urban and rural areas. Fifth, this study used a case-crossover design that individually matched potential confounding factors by month, year, and other time-invariant variables and controlled for time-varying patterns, as demonstrated by the minimal differences in meteorological variables between case and control days.

### Limitations

This study also has several limitations. First, the case-crossover design does not allow estimation of mortality rate increase associated with long-term exposure to air pollution. Long-term risks in the same study population have been estimated elsewhere.<sup>40</sup> Second, because this study used residential zip code to ascertain exposure level rather than exact home address or place of death, some measurement error is expected. Third, the Medicare population primarily consists of individuals older than 65 years, which limits the generalizability of findings to younger populations. However, because more than two-thirds of deaths in

the United States occur in people older than 65 years of age, and air pollution-related health risk rises with age, the Medicare population in this study includes most cases of air pollution-induced mortality. Fourth, Medicare files do not report cause-specific mortality. Fifth, the most recent data used in this study are nearly 5 years old, and it is uncertain whether exposures and outcomes would be the same with more current data.

## Conclusions

In the US Medicare population from 2000 to 2012, short-term exposures to PM<sub>2.5</sub> and warm-season ozone were significantly associated with increased risk of mortality. This risk occurred at levels below current national air quality standards, suggesting that these standards may need to be reevaluated.

### ARTICLE INFORMATION

**Accepted for Publication:** November 20, 2017.

**Author Contributions:** Mr Di had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. Mr Di and Dr Dai contributed equally to this study.

**Concept and design:** Di, Dai, Zanobetti, Schwartz, Dominici.

**Acquisition, analysis, or interpretation of data:** All authors.

**Drafting of the manuscript:** Di, Dai, Choirat, Dominici.

**Critical revision of the manuscript for important intellectual content:** All authors.

**Statistical analysis:** Di, Dai, Choirat, Schwartz, Dominici.

**Obtained funding:** Zanobetti, Schwartz, Dominici.

**Administrative, technical, or material support:** Wang, Choirat.

**Supervision:** Zanobetti, Schwartz, Dominici.

**Conflict of Interest Disclosures:** All authors have completed and submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Mr Di reported receiving grants from the National Institutes of Health (NIH), Environmental Protection Agency (EPA), Health Effects Institute (HEI), and the National Cancer Institute. Dr Zanobetti reported receiving grants from the NIH, HEI, and EPA. Dr Choirat reported receiving grants from the NIH and EPA. Dr Schwartz reported receiving funding from the US Department of Justice, NIH, EPA, and HEI. Dr Schwartz is an expert consultant of the US Department of Justice regarding health impacts of Clean Air Act violations. No other disclosures were reported.

# Ambient Particulate Matter Air Pollution Exposure and Mortality in the NIH-AARP Diet and Health Cohort

George D. Thurston,<sup>1</sup> Jiyoung Ahn,<sup>2</sup> Kevin R. Cromar,<sup>1</sup> Yongzhao Shao,<sup>2</sup> Harmony R. Reynolds,<sup>3</sup> Michael Jerrett,<sup>4</sup> Chris C. Lim,<sup>1</sup> Ryan Shanley,<sup>2</sup> Yikyung Park,<sup>5,6</sup> and Richard B. Hayes<sup>2</sup>

<sup>1</sup>Department of Environmental Medicine, New York University School of Medicine, Tuxedo, New York, USA; <sup>2</sup>Department of Population Health, and <sup>3</sup>Cardiovascular Clinical Research Center, Department of Medicine, New York University School of Medicine, New York, New York, USA; <sup>4</sup>School of Public Health, University of California, Berkeley, Berkeley, California, USA; <sup>5</sup>Division of Public Health Sciences, Department of Surgery, Washington University School of Medicine, St. Louis, Missouri, USA; <sup>6</sup>National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland, USA

**BACKGROUND:** Outdoor fine particulate matter ( $\leq 2.5 \mu\text{m}$ ;  $\text{PM}_{2.5}$ ) has been identified as a global health threat, but the number of large U.S. prospective cohort studies with individual participant data remains limited, especially at lower recent exposures.

**OBJECTIVES:** We aimed to test the relationship between long-term exposure  $\text{PM}_{2.5}$  and death risk from all nonaccidental causes, cardiovascular (CVD), and respiratory diseases in 517,041 men and women enrolled in the National Institutes of Health-AARP cohort.

**METHODS:** Individual participant data were linked with residence  $\text{PM}_{2.5}$  exposure estimates across the continental United States for a 2000–2009 follow-up period when matching census tract-level  $\text{PM}_{2.5}$  exposure data were available. Participants enrolled ranged from 50 to 71 years of age, residing in six U.S. states and two cities. Cox proportional hazard models yielded hazard ratio (HR) estimates per  $10 \mu\text{g}/\text{m}^3$  of  $\text{PM}_{2.5}$  exposure.

**RESULTS:**  $\text{PM}_{2.5}$  exposure was significantly associated with total mortality (HR = 1.03; 95% CI: 1.00, 1.05) and CVD mortality (HR = 1.10; 95% CI: 1.05, 1.15), but the association with respiratory mortality was not statistically significant (HR = 1.05; 95% CI: 0.98, 1.13). A significant association was found with respiratory mortality only among never smokers (HR = 1.27; 95% CI: 1.03, 1.56). Associations with  $10\text{-}\mu\text{g}/\text{m}^3$   $\text{PM}_{2.5}$  exposures in yearly participant residential annual mean, or in metropolitan area-wide mean, were consistent with baseline exposure model results. Associations with  $\text{PM}_{2.5}$  were similar when adjusted for ozone exposures. Analyses of California residents alone also yielded statistically significant  $\text{PM}_{2.5}$  mortality HRs for total and CVD mortality.

**CONCLUSIONS:** Long-term exposure to  $\text{PM}_{2.5}$  air pollution was associated with an increased risk of total and CVD mortality, providing an independent test of the  $\text{PM}_{2.5}$ –mortality relationship in a new large U.S. prospective cohort experiencing lower post-2000  $\text{PM}_{2.5}$  exposure levels.

Ambient particulate matter air pollution exposure and mortality in the NIH-AARP Diet and Health cohort. *Environ Health Perspect* 124:484–490; <http://dx.doi.org/10.1289/ehp.1509676>

## Introduction

Over the past several decades, numerous published epidemiologic studies have documented a consistent association between long-term exposure to fine particulate matter mass ( $\leq 2.5 \mu\text{m}$ ;  $\text{PM}_{2.5}$ ) air pollution and an increase in the risk of mortality around the globe (e.g., Beelen et al. 2014; Brook et al. 2010; Crouse et al. 2012; Dockery et al. 1993; Eftim et al. 2008; Ostro et al. 2010; Ozkaynak and Thurston 1987; Pope et al. 1995, 2002, 2004). Pope and collaborators notably found elevated relative risks of cardiovascular (CVD) mortality in association with long-term  $\text{PM}_{2.5}$  exposure [hazard ratio (HR) per  $10 \mu\text{g}/\text{m}^3 = 1.12$ ; 95% confidence interval (CI): 1.08, 1.15] in the largest and most definitive U.S. nationwide cohort considered to date (Pope et al. 2002, 2004), providing a cardiovascular mortality HR of 1.12 per  $10 \mu\text{g}/\text{m}^3$  (95% CI: 1.08, 1.15). However, existing U.S. cohort studies of  $\text{PM}_{2.5}$  health effects are still being questioned (e.g., Reis 2013). In addition, particulate matter air

pollution levels have been declining in recent years in the United States, so there is a need to confirm whether studies conducted in the past at higher levels are replicable today. Thus, it is important to test these associations in another large U.S. cohort with detailed individual-level risk factor information on participants, especially one for which pollution exposures can be estimated at the individual participant residence level, and in more recent lower  $\text{PM}_{2.5}$  exposure years, as we report here. This research addresses these needs using the newly available U.S. National Institutes of Health–AARP Diet & Health cohort (NIH-AARP Study) (Schatzkin et al. 2001).

## Methods

**Study population.** The NIH-AARP Study was initiated when members of the AARP, 50–71 years of age from six U.S. states (California, Florida, Louisiana, New Jersey, North Carolina, and Pennsylvania) and two metropolitan areas (Atlanta, Georgia, and Detroit, Michigan), responded to a mailed

questionnaire in 1995 and 1996. Details of the NIH-AARP Study have been described previously (Schatzkin et al. 2001). Among 566,398 participants enrolled in the NIH-AARP cohort and available for analysis in 2014, we first excluded for this analysis those individuals for whom the forms were filled out by a proxy ( $n = 15,760$ , or 2.8%); who moved out of their study region before January 2000 ( $n = 13,863$ , or 2.4%); who died before 1 January 2000 ( $n = 21,415$ , or 3.8%); and those for whom census-level outdoor  $\text{PM}_{2.5}$  exposure was not estimable using the methods discussed below ( $n = 737$ , or 0.1%). After accounting for overlapping exclusions, the analytic cohort includes 517,041 (91.3%) participants for whom matching  $\text{PM}_{2.5}$  air pollution data were available. The NIH-AARP cohort questionnaires elicited information on demographic and anthropometric characteristics, dietary intake, and numerous health-related variables (e.g., marital status, body mass index, education, race, smoking status, physical activity, and alcohol consumption) at enrollment only. Contextual environment characteristics (e.g., median income) for the census tract of each of this cohort's participants have also been compiled for this population by the NIH-AARP Study (NIH-AARP 2006), allowing us to also incorporate contextual socioeconomic variables at the census-tract level. All participants provided informed consent before completing the study

questionnaire. The study was approved by the institutional review boards of the National Cancer Institute and New York University School of Medicine.

**Cohort follow-up and mortality ascertainment.** Vital status was ascertained through a periodic linkage of the cohort to the Social Security Administration Death Master File and follow-up searches of the National Death Index Plus for participants who matched to the Social Security Administration Death Master File (unpublished data, available on request from <https://www.ssa.gov/dataexchange/>), cancer registry linkage, questionnaire responses, and responses to other mailings. Participants were followed for address changes using the U.S. Postal Service's National Change of Address database, responses to other study-related mailings such as newsletters, and directly from cohort members' notifications (Michaud et al. 2005). We used the *International Classification of Diseases, 9th Revision* (ICD-9) and the *International Statistical Classification of Diseases, 10th Revision* to define death due to CVD (ICD-10: I00–I99), nonmalignant respiratory disease (ICD-10: J00–J99), and deaths from nonexternal and nonaccidental deaths (ICD-10 A00–R99). During the follow-up period considered here (2000 through 2009), 86,864 (16.8%) participants died, of whom 84,404 (97.2% of deaths) participants died of nonexternal and nonaccidental causes.

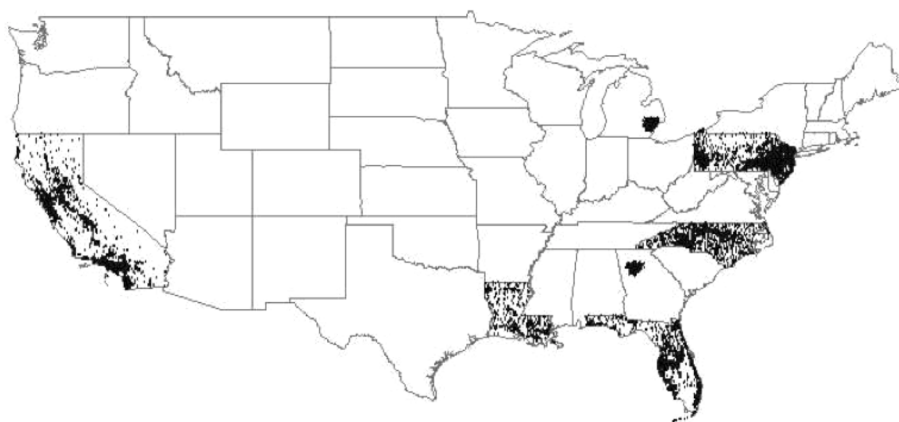

**Air pollution exposure assessment.** Outdoor annual PM<sub>2.5</sub>-related exposures at the census-tract level for residences at NIH-AARP cohort entry were estimated using data from the U.S. Environmental Protection Agency (EPA) nationwide Air Quality System (AQS, formerly AIRS) (<http://www.epa.gov/airdata/>). The nationwide AQS Network includes nearly 3,000 sites, has operated since the 1970s, and has included measurement of PM<sub>2.5</sub> mass since mid-1999. The year 2000 was selected as the start of follow-up in this study because that is the first full year that outdoor PM<sub>2.5</sub> exposure data were available nationwide. The contiguous U.S. map in Figure 1 displays the census tracts in which the members of this cohort resided at the start of the study. Private residence locations were not included in the original NIH-AARP Cohort data set in order to protect participant privacy. As a result, we employed census tract centroid estimates of monthly average PM<sub>2.5</sub> mass exposures available through the year 2008, as obtained from a published hybrid land-use regression (LUR) geostatistical model (Beckerman et al. 2013), and as matched with individuals by NIH to further protect participant anonymity. Exposure was considered only through 2008 because the time-dependent model matched deaths with exposure in each prior year, and follow-up ended in 2009 for these analyses.

These estimates used ambient AQS PM<sub>2.5</sub> as the dependent variable and traffic and land use information as predictors (Beckerman et al. 2013). Residuals from this model were interpolated with a Bayesian maximum entropy (BME) model, and the estimates from the LUR and BME were combined post hoc to derive monthly estimates of PM<sub>2.5</sub>. To allow investigation of possible confounding by O<sub>3</sub> exposure, annual primary metropolitan statistical area (PMSA) mean ozone (O<sub>3</sub>) exposures were also estimated for the year 2000 by averaging annual O<sub>3</sub> means from all ambient monitoring sites with > 75% of possible days of data in each PMSA (including 391 sites among 93 PMSAs) (U.S. EPA 2014). The PMSA mean PM<sub>2.5</sub> mass concentrations in 2008, at the end of the exposure period, were lower than but highly correlated with their paired PMSA mean concentration in 2000 ( $R^2 = 0.77$ ), suggesting that the spatial rank ordering of PM<sub>2.5</sub> concentrations remained consistent over the follow-up period. However, the number of cohort participants living below the U.S. annual PM<sub>2.5</sub> standard (12 µg/m<sup>3</sup>) increased over time, rising steadily from only 33% of cohort participants in 2000 (mean ± SD = 13.6 ± 3.6 µg/m<sup>3</sup>) up to 78% of cohort participants living below the 12 µg/m<sup>3</sup> annual PM<sub>2.5</sub> standard in 2008 (mean ± SD = 10.2 ± 2.3 µg/m<sup>3</sup>). Therefore, to incorporate these exposure level changes over the follow-up time, we also developed annual mean exposures at the census tract centroid of each participant's residence at baseline to incorporate into a time-dependent sensitivity analysis of the PM<sub>2.5</sub>–mortality association, with censoring for those known to have moved.

**Statistical methods.** Person-years of follow-up were included for each participant from 1 January 2000 to the date of death, the end of follow-up (31 December 2009), or the date the participant moved out of the state or city where s/he lived at enrollment, whichever occurred first. This period was selected because that is the time period

for which outdoor PM<sub>2.5</sub> exposure estimates were available nationwide at the census-tract level for matching with the cohort mortality data (Beckerman et al. 2013). For the time-independent exposure model, the exposure metric was each participant's annual mean enrollment census tract–centroid PM<sub>2.5</sub> exposure in the first year of this mortality analysis, 2000, which was the first complete year of PM<sub>2.5</sub> data availability across the United States. In addition, we also considered a time-dependent (annual mean) model, for which annual mean census tract–level exposure to PM<sub>2.5</sub> was treated as time-varying, with a 1-year lag. For example, mortality risk during 2000 was related to each participant's enrollment residence census tract–specific average PM<sub>2.5</sub> for 1999.

We used the Cox proportional hazards models (Cox and Oakes 1984; Fleming and Harrington 1991) to estimate relative risks (RRs) of mortality and 95% confidence intervals (CIs) in relation to ambient PM<sub>2.5</sub> (per 10 µg/m<sup>3</sup>). In multivariate models including individual-level variables, we treated age (in 3-year groupings), sex and region (six U.S. States and two municipalities of residence at study entry) as strata and adjusted for the following individual covariates and potential risk factors at enrollment: race (non-Hispanic white, non-Hispanic black, other), education (< 8 years, 8–11 years, high school, some college, college graduate), marital status (married, never married, or other, including widowed/divorced/separated and unknown), body mass index (BMI; < 18.5, 18.5 to < 25.0, 25.0 to < 30.0, 30 to < 35, and ≥ 35 kg/m<sup>2</sup>), alcohol consumption (none, < 1, 1–2, 2–5, and ≥ 5 drinks per day), and smoking history (never smoker, former smoker who quit at least 1 year ago of ≤ 1 pack/day, former smoker who quit at least 1 years ago of > 1 pack/day, quit less than 1 year ago or current smoker of ≤ 1 pack/day, quit less than 1 year ago or current smoker of > 1 pack/day). We also included two contextual characteristics of the

**Figure 1.** Continental U.S. map of NIH-AARP study participants' census tracts.

participants' residential census tracts found to modify the PM<sub>2.5</sub>–mortality HR estimates and have statistical significance in our analyses (data not shown): *a*) median census tract household income; and *b*) percent of census tract population with less than a high school education, based on the 2000 decennial census for the residence at study entry, as included in the cohort data set (NIH-AARP 2006). Potential effect modification was assessed by including multiplicative interaction terms between PM<sub>2.5</sub> concentrations and each covariate [e.g., sex, age < 65 or ≥ 65 years, age and sex combined, education (< high school, high school, > high school), and smoking (never, former, current) at baseline] in the proportional hazards models. Likelihood ratio statistic *p*-values (two-sided) comparing model fit with and without interaction terms were used to test the statistical significance of each interaction, with *p*-values of < 0.05 defined as statistically significant. Statistical analyses were carried out in SAS (version 9.3; SAS Institute Inc.) and R (version 3.0.1), using the “survival” package (R Core Team 2013).

Additional sensitivity analyses were conducted, including models without adjusting for contextual variables; limiting the analysis to California residents; without censoring data after people moved; adjusting for O<sub>3</sub>, and using PM<sub>2.5</sub> exposures estimated at the metropolitan area average level (rather than at the census tract level). In addition, other contextual characteristics were also considered: *a*) Gini coefficient, a metric of income inequality; *b*) percent of census tract population who are black; *c*) percent of census tract population who are unemployed; and *d*) percent of census tract population living below the poverty level, but were not included in the final model, as addition of these variables did not significantly affect results. To allow more direct comparisons with past work applying random effects methods (e.g., Krewski et al. 2009), we also evaluated HRs in relation to baseline (2000) PM<sub>2.5</sub> exposure levels while incorporating random effects for state of residence using the “coxme” package in R.

To show how the shape of the PM<sub>2.5</sub>–mortality relationship response varies with concentration in this cohort, PM<sub>2.5</sub> natural spline (ns) plots with 4 degrees of freedom (df) were prepared for both total (all cause) and cardiovascular mortality using standard Cox models for the baseline case, stratified by age and sex, and adjusted for all individual-level covariates and contextual variables, as described above.

## Results

The cohort was exposed to a wide range of PM<sub>2.5</sub> concentrations (Table 1), with a concentration range similar to the nation as a whole (U.S. EPA 2009). Except for race

(for which Table 1 indicates a rising exposure with increasing percentage of black participants), cohort characteristics were generally similar across PM<sub>2.5</sub> exposure level, limiting the potential for confounding in our PM<sub>2.5</sub> mortality relationship analyses.

In our time-independent baseline exposure Cox model analyses of the selected cohort (using the study entry tract of residence PM<sub>2.5</sub> mean as the exposure reference for each participant), higher levels of ambient PM<sub>2.5</sub> exposure were significantly associated with increased mortality due to all causes of (nonaccidental) death (HR = 1.03 per 10 µg/m<sup>3</sup> PM<sub>2.5</sub>; 95% CI: 1.00, 1.05) and cardiovascular disease (HR = 1.10; 95% CI: 1.05, 1.15), as presented in Table 2. Stratified analyses by sex, age, and education for this cohort did not indicate significant differences in PM<sub>2.5</sub> effect estimates across categories (Table 2). However, although PM<sub>2.5</sub> exposure was not significantly associated overall with increased risk of respiratory mortality (HR = 1.05; 95% CI: 0.98, 1.13), an association was found for never smokers (HR = 1.27; 95% CI: 1.03, 1.56). Figure 2 graphically demonstrates, for the time-independent model, the monotonically rising nature of the concentration–response curve for both all-cause and CVD mortality (vs. a referent HR = 1.0 at the mean level of exposure).

A number of sensitivity analyses for alternative models were also conducted (Table 3). In general, associations were stronger and *p*-values were smaller when we did not adjust for census tract–level contextual environmental variables, including the association with respiratory mortality (HR = 1.09; 95% CI: 1.02, 1.18). Adding random-effects terms to the time-independent model yielded very similar results to those without random-effects terms. Time-dependent yearly exposure models gave comparable results to the year 2000 time-independent baseline exposure model for total mortality (HR = 1.03; 95% CI: 0.99, 1.05), CVD mortality (HR = 1.11; 95% CI: 1.06, 1.16), and respiratory mortality (HR = 1.05; 95% CI: 0.97, 1.15). Limiting the analysis to only California (the state with the largest number of cohort participants) gave similar results to the entire cohort. To assess the extent to which our censoring of those who moved out of the study state/city might have affected the results, we also present overall results for participants without that censoring, retaining those who moved after 2000, finding that it gave similar results to our base model case with censoring (as shown in Table 2). In addition, in a model that simultaneously also included exposure to the gaseous pollutant O<sub>3</sub> along with PM<sub>2.5</sub>, the PM<sub>2.5</sub> effect estimate was found to be still significant and its CVD mortality effect

estimate not statistically different from the model without the addition of O<sub>3</sub>, indicating the PM<sub>2.5</sub>–CVD mortality association to be robust to the addition of O<sub>3</sub>.

## Discussion

In this large prospective cohort study with detailed baseline individual-level risk factor information on study participants (e.g., smoking, BMI, alcohol use), we confirmed a monotonically increasing, and statistically significant, relationship between long-term exposure to PM<sub>2.5</sub> air pollution and both all-cause and CVD mortality, even at the decreased PM<sub>2.5</sub> levels experienced in the United States since 2000. Comparisons by sex, age, and education for this cohort did not indicate statistically significant differences in the mortality–PM<sub>2.5</sub> association across categories.

With significant overall associations with all-cause and cardiovascular mortality, the results presented here are consistent with many, but not all, of the prior published results examining PM<sub>2.5</sub> and mortality. We estimated a 3% increase (95% CI: 0, 5%) in all-cause mortality for a 10-µg/m<sup>3</sup> annual increase in PM<sub>2.5</sub> that, though statistically significant in this large cohort, is lower than many other past estimates. For example, a recent literature review reported a pooled effect estimate of 6% per 10 µg/m<sup>3</sup> PM<sub>2.5</sub> (95% CI: 4, 8%) for all-cause mortality (Hoek et al. 2013). Our overall estimate for CVD mortality (10% effect per 10 µg/m<sup>3</sup>; 95% CI: 5, 15%), agrees more closely with the pooled estimate for CVD mortality reported by Hoek et al. (2013) (11% per 10 µg/m<sup>3</sup>; 95% CI: 6, 16%).

Comparisons with the American Cancer Society (ACS) cohort, a similarly large nationwide cohort, provides an opportunity to evaluate the issue of association consistency over time in the United States. Although participants in the ACS cohort (Pope et al. 2002) were somewhat younger (mean 56 years at recruitment, vs. mean 65 years in the NIH-AARP cohort in 2000), and were exposed during that study's follow-up to pollution at an earlier period of time (when the mix of air pollution sources was likely different), it has a similar racial (> 90% white) and educational (> 50% post-high school education) composition, is of similar size (> 500,000 participants), and also spans the United States, making it probably the most similar U.S. cohort for comparison here. The ACS cohort reported that a 10-µg/m<sup>3</sup> increase in PM<sub>2.5</sub> was associated with a 4% increase in all-cause mortality (95% CI: 1, 8%) (Pope et al. 2002), which is consistent with the corresponding estimate from the present analysis (3% per 10 µg/m<sup>3</sup>; 95% CI: 0, 5%), as shown in Figure 3. Moreover,

the PM<sub>2.5</sub>–CVD mortality effect estimate reported for the ACS cohort (12% per 10 µg/m<sup>3</sup>; 95% CI: 8, 15%) (Pope et al. 2004) is very similar to the corresponding association in the NIH-AARP cohort (10% per 10 µg/m<sup>3</sup>; 95% CI: 5, 15%) (Figure 3). This new prospective cohort study's follow-up begins at approximately the time that most of the published ACS cohort's follow-up analyses ended, providing an independent test as to whether the effects continue to the lower PM<sub>2.5</sub> levels in the 21st century. The ACS cohort study started in 1982 with follow-up through 1998, with an annual PM<sub>2.5</sub> study period mean ± SD = 17.7 ± 3.7 µg/m<sup>3</sup>

(Pope et al. 2002); in contrast, this new NIH-AARP analysis started in 2000 with much lower study follow-up mean PM<sub>2.5</sub> of 12.2 ± 3.4 µg/m<sup>3</sup> through 2008. Our study therefore documents for the first time that the PM<sub>2.5</sub>–mortality effects still occur at the much lower post-2000 levels of exposures across the United States. In California, the ACS follow-up ended with a mean 1998–2002 PM<sub>2.5</sub> concentration of 14.1 µg/m<sup>3</sup> (Jerrett et al. 2013), versus a much lower end of follow-up mean 2008 PM<sub>2.5</sub> concentration of 10.4 µg/m<sup>3</sup> in the present study. Figure 3 provides comparative plots of these two cohort's PM<sub>2.5</sub> mortality estimates across

mortality outcomes, for both the United States and the State of California (Jerrett et al. 2013; Krewski et al. 2009; Pope et al. 2002, 2004), indicating consistency in their effect estimates, despite the notable decline in pollution levels after 2000.

We have also considered and compared effect estimates per 10 µg/m<sup>3</sup> PM<sub>2.5</sub> as a function of alternative PM<sub>2.5</sub> exposure metrics. In addition to the year 2000 base PM<sub>2.5</sub> exposure index, we also considered time-dependent annual mean exposure models for each mortality outcome that directly addressed the declining concentration levels of PM<sub>2.5</sub> exposures during follow-up.

<sup>a</sup>Number of participants in PM<sub>2.5</sub> quintile, after accounting for missing covariate data.

The fixed exposure model has the advantage that it provides results using methods directly comparable to those used in many past such analyses (e.g., the ACS CP-II cohort). We

found that the annual mean model yielded results consistent with the baseline (year 2000) exposure time-independent model. Lepeule et al. (2012) also found that varying

the exposure metric choice had little effect on  $PM_{2.5}$  effect estimates in their analysis of the Harvard Six Cities Study cohort. Not censoring those participants who moved out

Full baseline model with random effects	517,041	1.03 (1.00, 1.05)	1.10 (1.05, 1.14)	1.06 (0.99, 1.14)
Full baseline model with $O_3$	466,121	1.02 (0.99, 1.05)	1.07 (1.02, 1.12)	1.02 (0.94, 1.11)
Full baseline model retaining all who moved from study area after 2000	517,041	1.02 (1.00, 1.05)	1.10 (1.06, 1.15)	1.04 (0.97, 1.12)
Full baseline model for California only	160,209	1.02 (0.99, 1.04)	1.10 (1.05, 1.16)	1.01 (0.93, 1.10)

of the study areas between 2000 and 2006 ( $n = 28,923$ ) had little effect on these results. We also compared the results using both PMSA and census tract-level mean exposure metrics, finding similar and confirmatory results with either approach. This may suggest that the fact that people are mobile, and often do not stay at their home residence all day, may limit the exposure assessment accuracy gain derived from knowing home residence locale versus an area-wide average. Overall, we found that the PM<sub>2.5</sub>–mortality associations in this work are robust to various PM<sub>2.5</sub> exposure modeling choices.

Numerous past long-term PM<sub>2.5</sub>–mortality analyses have found higher relative risks among those with less education. For example, Krewski et al. (2000), in their reanalysis of the Six Cities and ACS cohorts, found that the relative risk of mortality associated with fine particles was greater among individuals with high school education or less, compared to those with more than high school education in the Six Cities Study, and that the fine particle air pollution mortality risk decreased significantly ( $p < 0.05$ ) with increasing educational attainment in the ACS cohort. They concluded that “it is possible that educational attainment is a marker for socioeconomic status, which in turn may be correlated with exposure to fine particle air pollution.” Similarly, Brunekreef et al. (2009) found in their NLCS (Netherlands Cohort Study on Diet and Cancer)–AIR cohort examination of long-term exposure to traffic air pollution that associations with mortality tended to be stronger in case-cohort participants with lower levels of education, but that differences between strata were not statistically significant. Ostro et al. (2008) also estimated stronger

associations with components of PM<sub>2.5</sub> among individuals with lower educational attainment, attributing this trend to the effects of lower socioeconomic status. However, no such trend was found in this NIH-AARP cohort, perhaps because the reported annual incomes of this cohort did not vary with PM<sub>2.5</sub> concentration (Table 1). Indeed, although the association of education with median income in this cohort was strong ( $r = 0.49$ ), the correlation between PM<sub>2.5</sub> and median income was much lower ( $p = 0.03$ ). Thus, it may be that the lack of a strong socioeconomic–PM<sub>2.5</sub> covariation in this cohort is the reason we did not see the mortality effect modification by education status found in past studies.

This study has both strengths and limitations relative to past such studies. One strength is that we have employed estimates of PM<sub>2.5</sub> exposure at the participant residence census tract level, rather than applying the overall county or metropolitan area average exposure that has been used in some major prior studies (e.g., the Medicare and ACS cohorts, respectively) (Eftim et al. 2008; Krewski et al. 2009). In addition, most previous studies have assigned only a single fixed exposure level for each study participant (e.g., at the start of the follow-up), whereas we also considered a sensitivity model applying time-varying exposure estimates to address the declining PM<sub>2.5</sub> exposure levels over time. Another strength of this study is that covariate risk factors were collected at the individual level, but a limitation is that this was ascertained only at enrollment, and we could not account for temporal changes in risk factors (e.g., smoking and BMI) during follow up. Another limitation is that, other than knowing if and when participants leave the NIH-AARP

cohort study areas, we presently lack information on residence location after those participants moved out of the study region. Despite these limitations, as discussed above, our derived effect estimates were found to be largely consistent with other PM<sub>2.5</sub> mortality results, notably the ACS cohort study (Pope et al. 2002, 2004), the only prior prospective U.S. cohort study of such size with detailed individual-level risk factor information.

## Conclusions

Long-term exposure to PM<sub>2.5</sub> air pollution was associated with a significant increase in CVD and total nonaccidental mortality in the cohort as a whole, as well as with a significant increase in respiratory mortality among never smokers, in a new, large, U.S. cohort having detailed individual level participant data and census tract-level PM<sub>2.5</sub> exposure information. This independent evaluation of the PM<sub>2.5</sub>–mortality association, in this new large cohort, was robust to various model specification and PM<sub>2.5</sub> exposure assessment sensitivity analyses, and has found effect estimates (per 10  $\mu\text{g}/\text{m}^3$  of PM<sub>2.5</sub> exposure) that are consistent with past estimates, even at the much lower PM<sub>2.5</sub> air pollution levels experienced in the United States since 2000.

# Chronic Exposure to Fine Particles and Mortality: An Extended Follow-up of the Harvard Six Cities Study from 1974 to 2009

Johanna Lepeule,<sup>1</sup> Francine Laden,<sup>1,2,3</sup> Douglas Dockery,<sup>1,2,3</sup> and Joel Schwartz<sup>1,2,3</sup>

<sup>1</sup>Department of Environmental Health, and <sup>2</sup>Department of Epidemiology, Harvard School of Public Health, Boston, Massachusetts, USA; <sup>3</sup>Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA

**BACKGROUND:** Epidemiologic studies have reported associations between fine particles (aerodynamic diameter  $\leq 2.5 \mu\text{m}$ ;  $\text{PM}_{2.5}$ ) and mortality. However, concerns have been raised regarding the sensitivity of the results to model specifications, lower exposures, and averaging time.

**OBJECTIVE:** We addressed these issues using 11 additional years of follow-up of the Harvard Six Cities study, incorporating recent lower exposures.

**METHODS:** We replicated the previously applied Cox regression, and examined different time lags, the shape of the concentration–response relationship using penalized splines, and changes in the slope of the relation over time. We then conducted Poisson survival analysis with time-varying effects for smoking, sex, and education.

**RESULTS:** Since 2001, average  $\text{PM}_{2.5}$  levels, for all six cities, were  $< 18 \mu\text{g}/\text{m}^3$ . Each increase in  $\text{PM}_{2.5}$  ( $10 \mu\text{g}/\text{m}^3$ ) was associated with an adjusted increased risk of all-cause mortality ( $\text{PM}_{2.5}$  average on previous year) of 14% [95% confidence interval (CI): 7, 22], and with 26% (95% CI: 14, 40) and 37% (95% CI: 7, 75) increases in cardiovascular and lung-cancer mortality ( $\text{PM}_{2.5}$  average of three previous years), respectively. The concentration–response relationship was linear down to  $\text{PM}_{2.5}$  concentrations of  $8 \mu\text{g}/\text{m}^3$ . Mortality rate ratios for  $\text{PM}_{2.5}$  fluctuated over time, but without clear trends despite a substantial drop in the sulfate fraction. Poisson models produced similar results.

**CONCLUSIONS:** These results suggest that further public policy efforts that reduce fine particulate matter air pollution are likely to have continuing public health benefits.

**KEY WORDS:** air pollution, cohort studies, concentration–response, follow-up studies, lag, lung cancer, mortality, particles,  $\text{PM}_{2.5}$ , threshold. *Environ Health Perspect* 120:965–970 (2012). <http://dx.doi.org/10.1289/ehp.1104660> [Online 28 March 2012]

All-cause, cardiopulmonary, cardiovascular, and lung-cancer mortality have been associated with chronic air pollution exposure in prospective studies that controlled for individual covariates (Abbey et al. 1999; Beelen et al. 2008b; Beeson et al. 1998; Cao et al. 2011; Dockery et al. 1993; Eftim et al. 2008; Filleul et al. 2005; Gehring et al. 2006; Katanoda et al. 2011; Laden et al. 2006; Miller et al. 2007; Naftstad et al. 2004; Ostro et al. 2010; Pope et al. 2002; Puett et al. 2009; Yorifuji et al. 2011). The studies that specifically considered lung-cancer mortality associations with fine particles (aerodynamic diameter  $< 2.5 \mu\text{m}$ ;  $\text{PM}_{2.5}$ ), all found positive associations (Beelen et al. 2008b; Dockery et al. 1993; Laden et al. 2006; McDonnell et al. 2000), although this association was only statistically significant ( $p < 0.05$ ) in the American Cancer Society study (ACS) (Pope et al. 2002; Turner et al. 2011).

Although compelling evidence supports the harmful effects of  $\text{PM}_{2.5}$  on longevity, concerns have been raised regarding the sensitivity of the results to model specifications. In particular, Moolgavkar (2005, 2007) suggested that covariates may not be proportional and hence were not controlled for properly in proportional hazards models; that the concentration–response relation may not be linear; and that there are few observations at levels as low as or below the

current World Health Organization and U.S. Environmental Protection Agency (EPA) air quality standards. In addition, the relative toxicity of particle elements is still controversial, and most of the recent reduction in  $\text{PM}_{2.5}$  concentrations in the United States has come from sulfate control. Hence it is of interest whether the concentration–response curve has changed over time as particle composition has changed. Health impact assessments in the United States assume that health benefits of reducing particles are only fully realized after 20 years (U.S. EPA 2010), so examination of the lag between exposure and mortality is also relevant for consideration of changes in the standard.

Our goal was to test the robustness of the association between chronic exposure to  $\text{PM}_{2.5}$  and mortality observed in the original study (Dockery et al. 1993), and the first extended follow-up of the Harvard Six Cities study (Laden et al. 2006) by replicating the analyses using 11 additional years of follow-up with exposures well below the U.S. annual standard ( $15 \mu\text{g}/\text{m}^3$ ) (U.S. EPA 1997). We examined different lags of exposure, tested the shape of the  $\text{PM}_{2.5}$  concentration–mortality relationship, tested for changes in this slope over time, and relaxed the proportion assumption by allowing the effects of covariates to vary each year. We reexamined the association of  $\text{PM}_{2.5}$  with specific causes of death such as

lung cancer and examined the effects of  $\text{PM}_{2.5}$  depending on participants' chronic conditions and smoking status.

## Methods

**Study population.** The Harvard Six Cities study population has been previously described (Dockery et al. 1993). Briefly, adults were randomly sampled from six cities in the eastern and midwestern United States between 1974 and 1977: in 1974, Watertown, Massachusetts; in 1975, Kingston and Harriman, Tennessee, and specific census tracts of St. Louis, Missouri; in 1976, Steubenville, Ohio, and Portage, Wyocena, and Pardeeville, Wisconsin; and in 1977, Topeka, Kansas. Information on age, sex, weight, height, educational level, smoking history, hypertension, and diabetes was collected by questionnaire at enrollment. All participants underwent spirometry tests at enrollment (Dockery et al. 1985) and chronic obstructive pulmonary disease (COPD) was defined as having

$$(\text{FEV}_1 \div \text{FVC}) < 70\%,$$

where  $\text{FEV}_1$  is forced expiratory volume in 1 sec, and FVC is forced vital capacity. This analysis, as in the previous analyses, was restricted to 8,096 white participants with acceptable pulmonary function measurements. The study was approved by the Harvard School of Public Health Human Subjects Committee and all participants signed an informed consent before participation.

**Mortality follow-up.** Vital status and cause of death were determined by searching the National Death Index (NDI) for calendar years 1979–2009. Deaths before the NDI started in 1979 were identified by next of kin and Social Security records, and the cause of death was determined by a certified nosologist

who reviewed death certificates (Dockery et al. 1993).

**Survival time.** Survival times were calculated from enrollment until death or the end of follow-up (31 December 2009). For the 6 participants who were lost to follow-up before 1979, the censored survival times were calculated from enrollment to date of the last follow-up contact plus 6 months or the first day of the NDI (1 January 1979), whichever came first. For each cause of death category, participants who died from another cause were censored at time of death.

**Air pollution estimates.** Annual PM<sub>2.5</sub> concentration was assigned for each participant until death or censoring. PM<sub>2.5</sub> concentration was measured in the participant's city by a centrally located monitor from 1979 to 1986–1988, depending on the city (Dockery et al. 1993). Therefore, the study has no spatial contrast on the within-city scale. PM<sub>2.5</sub> concentrations for the years before monitoring started were assumed to be equal to the earliest monitored year. From the end of monitoring until 1998, PM<sub>2.5</sub> concentration was estimated from PM<sub>10</sub> (aerodynamic diameter < 10 µm) data from U.S. EPA monitors and visibility (extinction) data from the National Weather Service (Laden et al. 2006). From 1999 through 2009, direct measurements of PM<sub>2.5</sub> were available from U.S. EPA monitors. For sensitivity analyses, we also predicted PM<sub>2.5</sub> for 1999–2009 (correlation between predicted and measured was 0.97) using the formula applied to derive exposure estimates during the earlier period when PM<sub>2.5</sub> was not measured.

**Statistical analysis.** We first replicated the original analysis separately for all-cause mortality, cardiovascular mortality as coded by the *International Classification of Diseases, 9th Revision* [ICD-9; World Health Organization (WHO) 1977] or the *10th Revision* [ICD-10; WHO 1992], 400.0–440.9, I10.0–I70.9, respectively, lung-cancer mortality (ICD-9 162, ICD-10 C33.0–C34.9), and COPD mortality (ICD-9 490.0–496.0, ICD-10 J40.0–J47.0) for the 36-year follow-up from 1974 to 2009 using a Cox proportional hazards model with follow-up time as the time scale (Dockery et al. 1993; Laden et al. 2006). PM<sub>2.5</sub> was included in each model as an annual time-dependent variable. The model was stratified by sex, age (1-year intervals) and time in the study (1-year intervals), so that each age/sex group had its own baseline hazard for each year of follow-up. The analysis was adjusted for potential confounders collected at baseline: smoking status (never, former, current), cumulative smoking (pack-years included separately for current and former smokers), educational level (< high-school, ≥ high school), and a linear and quadratic term for body mass index (BMI; kilograms per meter squared), using

the Cox proportional hazards model formulated as follows:

$$h_{is}(t) = h_{0s}(t) \exp[\beta_1 X_i + \beta_2 Z_i(t)], \quad [1]$$

where  $h_i$  is the instantaneous hazard probability of death for subject  $i$  in stratum  $s$  (defined by sex, age, and time in the study),  $h_{0s}(t)$  is the baseline hazard function,  $X_i$  is the vector of time-independent variables, and  $Z_i(t)$  is the vector of time-dependent variables. We evaluated models with 1-year (i.e., exposure during the year before death or censor) to 5-year lagged moving averages and chose the best fit model using Akaike's information criterion (AIC) (Akaike 1973). The best fit moving average was determined from participants who survived at least 5 years from enrollment, so that AIC criteria were evaluated among populations with comparable sizes. We then estimated mortality rate ratios (RR) associated with PM<sub>2.5</sub> exposure during the best fit moving average on the whole sample size. Once the best exposure window was determined, we fit a penalized spline model using a cubic regression spline with 12 knots to estimate the shape of the concentration–response relation, and chose the optimal degree of freedom by minimizing AIC and evaluated nonlinearity with a Wald test. We investigated whether PM<sub>2.5</sub> advanced date of death for participants with chronic conditions at enrollment. We also investigated the potential for effect modification of PM<sub>2.5</sub> on mortality by smoking status at enrollment using interaction terms between such variables and PM<sub>2.5</sub>. Finally, we tested the hypothesis that the effect of PM<sub>2.5</sub> changed over time by dividing the follow-up into four equally spaced time periods and testing interactions between period and PM<sub>2.5</sub>.

**Sensitivity analyses.** We performed sensitivity analyses using a second-degree polynomial distributed lag model to allow the effects of PM<sub>2.5</sub> exposure to be distributed from 1 to 5 years before death or censor (Lepeule et al. 2006; Schwartz 2000); using predicted PM<sub>2.5</sub> concentrations after 1999 instead of the measured PM<sub>2.5</sub>; considering only deaths from natural causes, with external causes of deaths (ICD-9 E800–E999, ICD-10 S00–T88 and V00–Y99) being censored at time of death; and considering only deaths that occurred in the state where the participants lived at enrollment. We next investigated the robustness of the results to alternative modeling assumptions by using a Poisson model with dummy variables for each year of follow-up, which is equivalent to a piecewise exponential proportionate hazard model with the baseline hazard changing each year (Laird and Oliver 1981):

$$\log \mu_{it} = \log E_{it} + \gamma_t T_t + \beta_1 X_i + \beta_2 Z_i(t), \quad [2]$$

where  $\mu_{it}$  is the expected value of the death indicator for subject  $i$  at time  $t$ ,  $E_{it}$  is the

exposure duration of subject  $i$  at time  $t$  ( $\log E_{it}$  being the offset),  $T_t$  is the vector of dummy variables for time by 1 year (piecewise baseline hazard),  $X_i$  is the vector of the time-independent covariates, and  $Z_i(t)$  is the vector of time-dependent variables. Using this Poisson survival analysis, we first compared the results to the Cox model and then relaxed the proportionate hazard assumption for sex, education, and cumulative smoking by including interaction terms of these variables with each year of follow-up. As an alternative to the previous analyses (Dockery et al. 1993; Laden et al. 2006), we used age in 5-year groups as the time scale, and adjusted the model for time trends (linear term). For specific causes of death, convergence issues led us to group age by 10 years. We then fit penalized spline models. Because RRs may vary over time and period-specific RRs may be biased, we used the Poisson model to calculate adjusted survival curves (Hernan 2010). We included product terms between PM<sub>2.5</sub> and time in model 2 [Equation 2], thereby allowing the effect of PM<sub>2.5</sub> to flexibly vary from year to year. We then predicted the survival probability for each year of follow-up for each participant under three scenarios using concentrations of PM<sub>2.5</sub> throughout the entire follow-up period equal to 10, 15, or 20 µg/m<sup>3</sup>.

$p$ -Values < 0.05 were considered statistically significant. All analyses were repeated separately for all- and specific-causes of deaths. Analyses were conducted with SAS software, version 9.2 (SAS Institute Inc., Cary, NC) and R statistical software, version 2.12.2 (R Foundation for Statistical Computing, Vienna, Austria).

## Results

**Study population.** The 8,096 participants were 25–74 years of age at enrollment (mean ± SD, 49.6 ± 13.4) and 54.7% were female. More than half of the participants had a high school degree or higher, 35.8% were current smokers, and 23.9% were former smokers and the average BMI was 25.8 ± 4.5. As for chronic conditions, 17.8% reported hypertension, 11.6% COPD, and 6.9% diabetes.

**Mortality rates and PM<sub>2.5</sub> levels.** At the end of 2009, there were 212,067 person-years of follow-up and 55.5% of the participants had died, among whom 40.8% died from cardiovascular diseases, 7.8% from lung cancer, and 5.5% from COPD (Table 1). Overall, PM<sub>2.5</sub> concentration decreased during the study period (Figure 1). After 1998, annual average levels declined by 1.8 µg/m<sup>3</sup> in St. Louis and by 10.5 µg/m<sup>3</sup> in Steubenville, whereas levels increased by 1.5 µg/m<sup>3</sup> in the Portage–Wyocena–Pardeeville area. Since 2000, all the cities experienced average PM<sub>2.5</sub> levels < 15 µg/m<sup>3</sup> except Kingston–Harriman and Steubenville, which had average concentrations of ≤ 18 µg/m<sup>3</sup>.

**Association between PM<sub>2.5</sub> and mortality.** Using the Cox proportional hazards model, statistically significant associations between PM<sub>2.5</sub> exposure and all-cause, cardiovascular, and lung-cancer mortality were observed (Table 2). The AIC indicated lag 1 (i.e., exposure during the previous year) to be the best fit exposure window for all-cause mortality [see Supplemental Material, Table 1 (<http://dx.doi.org/10.1289/ehp.1104660>)]. For cause-specific mortality, the best fit moving average differed between the Cox and the Poisson regressions. Because the differences in AIC were very small between the 1- and 5-year moving averages for both the Cox and Poisson regressions, we chose the longer of the two moving averages to produce more stable results, specifically, a 1- to 3-year moving average for cardiovascular and lung-cancer mortality, and a 1- to 5-year moving average for COPD mortality. Each 10- $\mu\text{g}/\text{m}^3$  increase in PM<sub>2.5</sub> was associated with a 14% increased risk of all-cause death [95% confidence interval (CI): 7%, 22%], a 26% increase in cardiovascular death (95% CI: 14%, 40%), and a 37% increase in lung-cancer death (95% CI: 7%, 75%). For both all-cause mortality and

specific causes of death, the model fit was better without the spline ( $p$ -values between 0.24 and 0.43), indicating a linear relationship with PM<sub>2.5</sub>. Results restricted to participants with chronic conditions at enrollment (i.e., hypertension, COPD, or diabetes) were consistent with those estimated for all participants (Table 2). Although, the interaction between smoking status and PM<sub>2.5</sub> was not statistically significant, there was a trend for a stronger estimated effect of PM<sub>2.5</sub> on mortality in current and former smokers. However, positive associations between PM<sub>2.5</sub> and all-cause and cardiovascular mortality were still evident in never smokers. RR for PM<sub>2.5</sub> fluctuated over time for all-cause mortality and specific causes of death, without clear trends (Table 2).

**Sensitivity analysis.** For both all causes and specific causes of death, the cumulative effects estimated from the polynomial distributed lag model were similar to the effect estimates obtained with the selected moving averages (Table 2). However, the five lags were too correlated (between 0.90 and 0.96) to disentangle the relative importance of each one. Using predicted PM<sub>2.5</sub> instead of measured PM<sub>2.5</sub> for exposures after 1999, excluding the

138 deaths from external causes and excluding the 702 participants who died in a state other than the state where they lived at enrollment, did not change the results (data not shown) except for the lung-cancer mortality association with PM<sub>2.5</sub>, which was slightly attenuated (increased risk of 28%; 95% CI: -2%, 67% compared with 37%; 95% CI: 7%, 75%) when the 702 participants were excluded.

With the Poisson framework, using basic assumptions, relaxed proportionate hazard assumption for covariates, or age as the time scale, the effect estimates and  $p$ -values fluctuated slightly but without any notable change in the results compared with estimates from the Cox models for all-cause mortality and for specific-causes of death (data not shown). The penalized spline models also indicated linear concentration-response relationships without a threshold for PM<sub>2.5</sub> and mortality from all-causes and specific-causes [see Supplemental Material, Figure 1 (<http://dx.doi.org/10.1289/ehp.1104660>)]. With the Poisson survival analysis, we predicted survival assuming every participant was exposed to a constant concentration of PM<sub>2.5</sub> (10, 15, or 20  $\mu\text{g}/\text{m}^3$ ) during the entire follow-up period. Adjusted

**Table 1.** Number of participants, mortality, and average PM<sub>2.5</sub> levels in the Harvard Six Cities study, 1974–2009.

Characteristic	Six cities (combined)	Steubenville	Kingston–Harriman	St. Louis	Watertown	Topeka	Portage–Wyocena– Pardeeville
Participants ( $n$ )	8,096	1,346	1,258	1,292	1,332	1,238	1,630
Person-years ( $n$ )	212,067	33,276	33,067	32,225	36,818	32,877	43,804
Cause of death							
All causes ( $n$ [%])	4,495 (55.5)	822 (61.1)	733 (58.3)	827 (64.0)	700 (52.6)	617 (49.8)	796 (48.8)
Cardiovascular (%)	40.8	45.3	41.1	42.2	39.3	37.4	38.6
Lung cancer (%)	7.8	9.0	8.0	8.7	6.6	7.3	6.8
COPD (%)	5.5	4.9	7.0	5.1	4.9	7.3	4.6
1974–2009 average of individual PM <sub>2.5</sub> concentrations	15.9	23.6	19.1	16.7	14.0	12.2	11.4

**Figure 1.** Annual mean PM<sub>2.5</sub> levels during 1974–2009 in the Harvard Six Cities study.

for individual covariates, the lowest PM<sub>2.5</sub> concentration was associated with the highest survival (Figure 2). The three adjusted survival curves showed that the proportionate hazard was a reasonable assumption for PM<sub>2.5</sub> and that PM<sub>2.5</sub> effects were quite stable over time.

## Discussion

Including more recent observations with PM<sub>2.5</sub> exposures down to 8 µg/m<sup>3</sup>, we continued to find a statistically significant association between chronic exposure to PM<sub>2.5</sub> and all-cause and cardiovascular mortality. Furthermore, in the present extended follow-up, PM<sub>2.5</sub> exposure was also statistically significantly associated with lung-cancer mortality. Our study indicated no sensitivity of

the results for all-cause mortality and specific causes of death when we allowed the effects of smoking, education, and sex to vary over time, or when we used age as the time scale instead of follow-up time. Using very flexible modeling assumptions, our results did not show any rationale for change of PM<sub>2.5</sub> effect size over the whole study period, as indicated by the adjusted survival curves and the lack of a clear interaction of PM<sub>2.5</sub> with the four study periods. The concentration–response relationship was linear without any threshold, even at exposure levels below the U.S. annual 15-µg/m<sup>3</sup> standard (U.S. EPA 1997). Taken together with the results of a previous reanalysis of the Harvard Six Cities study (Krewski et al. 2005b), there is evidence for a robust

association between chronic PM<sub>2.5</sub> exposure and early mortality.

**Consistency of the results.** Our results indicated a statistically significant 14% increase in all-cause mortality for a 10-µg/m<sup>3</sup> annual increase in PM<sub>2.5</sub>, which is similar to the results of the previous follow-ups (Dockery et al. 1993; Laden et al. 2006). The Netherlands Cohort Study on Diet (NLCS–Air) in Europe (Beelen et al. 2008b), the Adventist Study (McDonnell et al. 2000), and the male Health Professionals Follow-up Study in the United States (Puett et al. 2011) did not show statistically significant associations between PM<sub>2.5</sub> and all-cause mortality. However, our current results are consistent with those from the ACS cohort (Pope et al. 2002), the Nurses' Health Study (Puett et al. 2009), and the Medicare cohort (Eftim et al. 2008), which indicated mortality increases ranging from 3–26% per 10-µg/m<sup>3</sup> increase in PM<sub>2.5</sub>.

The 26% increase in cardiovascular mortality for each 10-µg/m<sup>3</sup> increase in PM<sub>2.5</sub> exposure during the previous 3 years estimated in this extended follow-up is similar to the previous estimate (Laden et al. 2006). Although the NLCS–Air study (Beelen et al. 2008b) found no statistically significant association, the magnitude of the estimated effect reported here is between the 12% increase estimated for the ACS cohort (Pope et al. 2004) and the 76% increase estimated for the Women's Health Initiative study (Miller et al. 2007). Puett et al. (2009) also estimated a 100% increase in fatal coronary heart diseases for a 10-µg/m<sup>3</sup> increase in PM<sub>2.5</sub> during the prior year. Underlying mechanisms for the effects of PM<sub>2.5</sub> on cardiovascular mortality are still poorly understood, but changes in vasoconstriction might explain the associations (Anderson et al. 2011).

The previous extended follow-up of the Harvard Six Cities study showed an elevated, but not statistically significant, risk of lung-cancer mortality (Laden et al. 2006), whereas the present extended follow-up estimated a statistically significant 37% increase in lung-cancer mortality (for each 10-µg/m<sup>3</sup> increase in PM<sub>2.5</sub>), which is greater than that estimated for both the ACS cohort (14%) (Pope et al. 2002) and a Japanese cohort (27%) (Katanoda et al. 2011). Lungs are one of the organs that are most directly affected by particulate air pollution. Fine particles, which may carry toxic chemicals of carcinogenic potential (Laden et al. 2000), can reach lung alveoli where the clearance is slow (Pinkerton et al. 1995) and induce durable pulmonary and systemic inflammation (Riva et al. 2011). Recent findings in the ACS cohort indicated that a 10-µg/m<sup>3</sup> increase in PM<sub>2.5</sub> concentration was associated with a statistically significant 15% to 27% increase in lung-cancer mortality in never smokers (Turner et al. 2011).

**Table 2.** Adjusted<sup>a</sup> association between PM<sub>2.5</sub><sup>b</sup> and mortality, for the 8,096 participants and certain subpopulations of the Harvard Six Cities study, 1974–2009.

Cause of death/stratum-specific estimates according to characteristics at enrollment	n participants (n person-years)	RR (95% CI) for 10-µg/m <sup>3</sup> increase in PM <sub>2.5</sub>

1992–2000	6,391 (51,800)	1.31 (0.74, 2.31)
2001–2009	4,910 (38,340)	0.68 (0.25, 1.83)

<sup>a</sup>Cox proportional hazards model stratified by sex, age, and time in the study and adjusted for BMI, education, and smoking history. <sup>b</sup>PM<sub>2.5</sub> moving average was 1 year before death or censor for all-cause deaths, 1–3 years for cardiovascular and lung-cancer deaths, and 1–5 years for COPD deaths. <sup>c</sup>Estimates restricted to participants with the specified chronic condition.

We did not find such an association in our study, which might be due to a lack of statistical power (350 lung-cancer deaths, 26 among never smokers). However, estimated effects of PM<sub>2.5</sub> on all-cause and cardiovascular mortality were also statistically significant (or borderline significant) in never smokers, and higher in current smokers compared to never or former smokers (Table 2).

Regarding COPD mortality, we found a positive but not statistically significant risk of COPD death associated with PM<sub>2.5</sub> exposure. In the ACS cohort, Pope et al. (2004) estimated an unexpected inverse association between PM<sub>2.5</sub> exposure and COPD mortality, whereas Katanoda et al. (2011) estimated an inverse but not statistically significant association between PM<sub>2.5</sub> and COPD in a Japanese cohort.

**Chronic conditions at enrollment and mortality.** The central deposition of particles in lungs has been shown to be enhanced in COPD patients (Bennett et al. 1997). Although PM<sub>2.5</sub> has been associated with early mortality in COPD patients (Zanobetti et al. 2008), and ozone has been associated with early mortality in susceptible subjects (i.e., with COPD, diabetes, heart failure, or myocardial infarction) (Zanobetti and Schwartz 2011), our results did not indicate stronger associations in participants with such chronic conditions at enrollment compared with the population as a whole. This might have been due to a lack of statistical power as few participants had COPD ( $n = 942$ ) or diabetes ( $n = 563$ ) at enrollment.

**Exposure assessment.** Use of outdoor measurements from central monitoring stations as a proxy measure of mean personal exposure to PM<sub>2.5</sub> is prone to measurement error because the measures do not capture fine spatial contrasts that may occur within a city, which may bias the results. Recent reanalyses of the ACS cohort using land use regression models showed that the impact on the PM<sub>2.5</sub>–mortality association was heterogeneous depending on the city (Krewski et al. 2009). However, other recent studies have suggested that considering a more precise exposure model focused on the home address might not improve health effects estimates in terms of bias and variance (Kim et al. 2009; Lepeule et al. 2010; Szpiro et al. 2011). In the Harvard Six Cities study, there were not enough monitors in the cities to implement a land use regression model.

**Strengths and limitations.** Our results were adjusted for baseline factors, but there is potential for residual confounding for risk factors after enrollment and for unmeasured factors such as occupational exposures or medication use if those factors co-vary with PM<sub>2.5</sub>. Some other limitations are that we did not measure PM<sub>2.5</sub> in the same locations throughout the

study period, that death certificates might have listed misclassified specific causes of death, and that hypertension and diabetes were assessed by questionnaire only. An extensive body of methodological work has been performed regarding the sensitivity of estimated associations between long-term exposure to air pollution and mortality, especially for the ACS and Harvard Six Cities study cohorts. More specifically, it has been shown that results were robust to alternative model specifications, alternative metrics of PM<sub>2.5</sub>, and adjustment for individual and ecological risk factors such as occupational exposures and socioeconomic variables (Krewski et al. 2005a, 2005b). It was also shown that using a spatial covariance structure did not change the results (Pope et al. 2002), but with only six locations, that methodology is not applicable in our study. Whereas the primary analysis from the Harvard Six Cities study (Dockery et al. 1993) estimated associations were based on between-city contrasts in exposure, in the current study, with age used as time scale, the exposure relied on both between- and within-city contrasts, limiting the potential for residual cross-sectional confounding. The strengths of the present study are the randomly sampled participants and its extended follow-up through 2009, which included more observations of participants with lower exposures during recent years and provided more statistical power.

**Critical periods of PM<sub>2.5</sub> exposure.** Our results indicated that the best fit moving average for PM<sub>2.5</sub> was 1 year for all-cause mortality. For cardiovascular and lung-cancer mortality, no clear pattern was identified because of the high correlation between PM<sub>2.5</sub> concentrations in the 5 lagged years tested. These results suggest that PM<sub>2.5</sub> exposure can act to promote cardiovascular diseases

and lung-cancer growth, although the design of this study precludes us from determining whether PM<sub>2.5</sub> initiates these diseases as suggested by other studies (Beelen et al. 2008a; Beeson et al. 1998). These results agree with the literature (Gehring et al. 2006; Krewski et al. 2009; Puett et al. 2009; Schwartz et al. 2008) and suggest that health improvements can be expected almost immediately after a reduction in air pollution. This conclusion should be taken into account for cost–benefit analyses related to air pollution standards.

**Role of sulfates and public health implications.** Although RRs for PM<sub>2.5</sub> fluctuated over time, our extended follow-up did not indicate any clear pattern over time during the study period. Between 1979–1988 (Laden et al. 2000) and 2009 (Nehls and Akland 1973), the sulfates/PM<sub>2.5</sub> ratio for exposures measured for the Harvard Six Cities study dropped between 13% and 54%, depending on the city. If sulfates are unrelated to mortality, as some have argued (Grahame and Schlesinger 2005), the elimination of a substantial fraction of nontoxic material from PM<sub>2.5</sub> mass should result in a substantial increase in the PM<sub>2.5</sub> coefficient, which would otherwise have been suppressed by the large fraction of mass that was nontoxic. This was not the case, and hence our results indicate that sulfate particles are about as toxic as the average fine particle. This is consistent with the results of Pope et al. (2007), who found that the 2.5- $\mu\text{g}/\text{m}^3$  decrease in sulfate particle concentrations observed during an 8-month smelters strike were associated with a 2.5% decrease in the number of deaths in the region. In comparison, a 2.5- $\mu\text{g}/\text{m}^3$  decrease in PM<sub>2.5</sub> in our follow-up of the Harvard Six Cities study was associated with a 3.5% reduction in all-cause deaths, but that was for reductions in PM<sub>2.5</sub> lasting at least a year, not

**Figure 2.** Survival probabilities under three hypothetical scenarios: participants of the Harvard Six Cities study are exposed to 10, 15, or 20  $\mu\text{g}/\text{m}^3$  PM<sub>2.5</sub> during the entire follow-up period of 1974–2009.

8 months. Given that there were 2,423,712 deaths in the United States in 2007 (Xu et al. 2010) and that the average  $PM_{2.5}$  level was  $11.9 \mu\text{g}/\text{m}^3$  (U.S. EPA 2011), our estimated association between  $PM_{2.5}$  and all-cause mortality implies that a decrease of  $1 \mu\text{g}/\text{m}^3$  in population-average  $PM_{2.5}$  would result in approximately 34,000 fewer deaths per year.

## Conclusion

Including recent observations with  $PM_{2.5}$  exposures well below the U.S. annual standard of  $15 \mu\text{g}/\text{m}^3$  and down to  $8 \mu\text{g}/\text{m}^3$ , the relationship between chronic exposure to  $PM_{2.5}$  and all-cause, cardiovascular, and lung-cancer mortality was found to be linear without a threshold. Our results were not sensitive to various model specifications. Furthermore, estimated effects of  $PM_{2.5}$  did not change over time, suggesting a stable toxicity of  $PM_{2.5}$ , even at lower exposure levels and with a lower sulfates proportion. These results suggest that further public policy efforts that reduce fine particulate matter air pollution are likely to have continuing public health benefits.

**UNITED STATES ENVIRONMENTAL PROTECTION AGENCY  
WASHINGTON D.C. 20460**

March 26, 2007

**OFFICE OF THE ADMINISTRATOR  
SCIENCE ADVISORY BOARD**

**Memorandum**

**SUBJECT:** Formation of Clean Air Scientific Advisory Committee (CASAC)  
NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel

**FROM:** Fred Butterfield */Signed/*  
Designated Federal Officer (DFO)  
Clean Air Scientific Advisory Committee  
EPA Science Advisory Board Staff Office (1400F)

**TO:** Vanessa Vu, Ph.D.  
Staff Director  
EPA Science Advisory Board (1400F)

**VIA:** Daniel Fort */Signed/*  
Ethics & FACA Policy Officer  
EPA Science Advisory Board Staff Office (1400F)

The Clean Air Scientific Advisory Committee (CASAC), which is comprised of seven members appointed by the EPA Administrator, was established under section 109(d)(2) of the Clean Air Act (CAA or Act) (42 U.S.C. 7409) as an independent scientific advisory committee. The CASAC provides advice, information and recommendations on the scientific and technical aspects of air quality criteria and National Ambient Air Quality Standards (NAAQS) under sections 108 and 109 of the Act. The CASAC is a Federal advisory committee chartered under the Federal Advisory Committee Act (FACA), as amended, 5 U.S.C., App. Section 109(d)(1) of the CAA requires that the Agency carry out a periodic review and revision, where appropriate, of the air quality criteria and the NAAQS for "criteria" air pollutants including oxides of nitrogen (NO<sub>x</sub>) and sulfur oxides (SO<sub>x</sub>).

On August 7, 2006 the SAB Staff Office announced in the *Federal Register* (71 FR 44695) the formation of the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel and solicited nominations for experts to supplement the statutory CASAC. This memorandum addresses the set of determinations that were necessary for forming the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel (Panel). Over the next two to three years, the Panel will provide advice and recommendations to the EPA Administrator on the scientific and technical aspects of the primary (health-based) policy-relevant science and the NAAQS for both NO<sub>x</sub> and SO<sub>x</sub>. Specifically, this will involve the Panel's review of EPA's updated draft Integrative Science Assessment (ISA) for NO<sub>x</sub> and SO<sub>x</sub> health effects; and subsequently, as the basis for possible revisions to the primary NAAQS for NO<sub>x</sub> and SO<sub>x</sub>, the Primary NO<sub>x</sub> and SO<sub>x</sub> Risk/Exposure Assessment (RA), and the

Primary NO<sub>x</sub> and SO<sub>x</sub> Policy Assessment (PA) to be published as an advance notice of proposed rulemaking (ANPR). This memo provides background information on this Panel, and addresses the following determinations:

- (A) The type of review body that will be used to conduct the review, the name of the Panel, and identification of the Panel Chair;
- (B) The types of expertise needed to address the general charge;
- (C) Financial conflict of interest considerations, including identification of parties who are potentially interested in or may be affected by the topic to be reviewed;
- (D) How regulations concerning “appearance of a lack of impartiality,” pursuant to 5 C.F.R. § 2635.502 apply to members of the Panel; and
- (E) How individuals were selected for the Panel.

#### **DETERMINATIONS:**

- (A) The type of review body that will be used to conduct the review, the name of the Panel, and identification of the Panel Chair.

The CASAC, augmented by additional subject-matter experts, known collectively as the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel, will conduct the ongoing review of, and offer advice and recommendations to the EPA Administrator concerning, the primary (health-based NAAQS for NO<sub>x</sub> and SO<sub>x</sub>. Dr. Rogene Henderson, the CASAC Chair, will chair this Panel. The CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel will comply with the provisions of FACA and all appropriate SAB Staff Office procedural policies.

- (B) The types of expertise needed to address the general charge.

Per the solicitation for nominees to form the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel that was published in the *Federal Register* on August 7, 2006 (see citation above), recognized, national-level experts were sought in one or more of the following six (6) disciplines to augment the expertise of the statutory CASAC:

(a) Atmospheric Science. Expertise in physical/chemical properties of nitrogen oxides and sulfur oxides and atmospheric processes involved in the formation, transport on urban to global scales, transformation of these pollutants in the atmosphere, and movement of the pollutants between media through deposition and other such mechanisms. Also, expertise in the evaluation of natural and anthropogenic sources and emissions of nitrogen oxides and sulfur oxides and resulting ambient levels due to natural sources, pertinent monitoring or measurement methods for these pollutants, and spatial and temporal trends in their atmospheric concentrations.

(b) Exposure and Risk Assessment/Modeling. Expertise in measuring human population exposure to nitrogen oxides and sulfur oxides and/or in modeling human population exposure to pollutants from ambient and indoor sources. Expertise in human health risk analysis modeling for nitrogen oxides and sulfur oxides related to respiratory and other non-cancer health effects.

(c) Dosimetry. Expertise in evaluation of the dosimetry of animal and human subjects, including identification of factors determining differential patterns of inhalation and/or deposition/uptake in respiratory tract regions that may contribute to differential susceptibility of human population subgroups and animal-to-human dosimetry extrapolations.

(d) Toxicology. Expertise in evaluation of experimental laboratory animal studies and *in vitro* studies of the effects of sulfur oxides and/or oxides of nitrogen on pulmonary and extra-pulmonary (*e.g.*, cardiovascular, immunological) endpoints.

(e) Controlled Human Exposure. Expertise in evaluations of controlled human exposure studies of the effects of nitrogen oxides and sulfur oxides on health and compromised (*e.g.*, having pertinent preexisting disease such as asthma) human adults and children, including physicians with experience in the clinical treatment of asthma and chronic lung diseases.

(f) Epidemiology and Biostatistics. Expertise in epidemiologic evaluation of the effects of exposures to ambient nitrogen oxides and sulfur oxides and/or other major air pollutants (*e.g.*, particulate matter, ozone, carbon monoxide) on human population groups, including mortality and morbidity effects (*e.g.*, respiratory symptoms, lung function decrements, asthma medication use, emergency department visits, respiratory-related hospital admissions). Also, expertise in associated biostatistics and/or health risk analysis.

(C) Financial conflict of interest considerations, including identification of parties who are potentially interested in or may be affected by the topic to be reviewed.

(a) Identification of parties who are potentially interested in or may be affected by the topic to be reviewed: The principal interested and affected parties for this topic are: (1) EPA; (2) State, regional and local air program (or air pollution control) agencies, and State regulatory officials; (3) State and local health officials; (4) research universities; (5) environmental interest groups/non-Governmental organizations (NGOs); (6) potentially responsible parties (PRP) and their contractors; and (7) various industry sectors interested in, or affected by, the current or any revised NAAQS for NO<sub>x</sub> and SO<sub>x</sub>, including the power-generating and automotive industries.

(b) Conflict of interest considerations: For Financial Conflict of Interest (COI) issues, the basic 18 U.S.C. § 208 provision states that: “An employee is prohibited from participating *personally and substantially* in an official capacity in any *particular matter* in which he, to his knowledge, or any person whose interests are imputed to him under this statute has a *financial interest*, if the particular matter will have a direct and predictable effect on that interest [emphasis added].” For a conflict of interest to be present, all elements in the above provision must be present. If an element is missing the issue does not involve a formal conflict of interest; however, the general provisions in the appearance of impartiality guidelines must still apply and need to be considered.

(i) Does the general charge to the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel involve a particular matter? A “particular matter” refers to matters that “...will involve deliberation, decision, or action that is focused upon the interests of specific people, or a discrete and identifiable class of people.” It does not refer to “...consideration or adoption of broad policy options directed to the interests of a large and diverse group of people.” [5 C.F.R. § 2640.103 (a)(1)]. A particular matter of general applicability means a particular matter that is

focused on the interests of a discrete and identifiable class of persons, but does not involve specific parties. [5 C.F.R. § 2640.102 (m)].

The CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel's activity in addressing the charge for the peer review of the draft NO<sub>x</sub> and SO<sub>x</sub> Primary ISA, RA and PA and related technical support documents will qualify as a *particular matter of general applicability* because the resulting advice will be part of a deliberation, and under certain circumstances the advice could involve the interests of a discrete and identifiable class of people but does not involve specific parties. That group of people constitutes those who are associated or involved with the potentially interested or affected parties, as identified in Section (3)(a) above.

(ii) Will there be personal and substantial participation on the part of Panel members? Participating personally means direct participation in this review. Participating substantially refers to involvement that is of significance to the matter under consideration. [5 C.F.R. § 2640.103(a)(2)]. For this review, the EPA Science Advisory Board (SAB) Staff Office has determined that *CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel members will be participating personally in the matter*. Panel members will be providing the Agency with advice and recommendations that is expected to include an assessment as to whether the proposed air quality criteria (by means of the ISA) accurately reflect the latest scientific knowledge useful in indicating the kind and extent of all identifiable effects on public health or welfare which may be expected from the presence of these pollutants (that is, NO<sub>x</sub> or SO<sub>x</sub>) in the ambient air. *Therefore, participation in this review will also be substantial.*

(iii) Will there be a direct and predictable effect on CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel members' financial interest? A direct effect on a participant's financial interest exists if "...a close causal link exists between any decision or action to be taken in the matter and any expected effect of the matter on the financial interest. ...A particular matter does not have a direct effect ...if the chain of causation is attenuated or is contingent upon the occurrence of events that are speculative or that are independent of, and unrelated to, the matter. A particular matter that has an effect on a financial interest only as a consequence of its effects on the general economy is not considered to have a direct effect." [5 C.F.R. § 2640.103(a)(i)] A predictable effect exists if, "...there is an actual, as opposed to a speculative, possibility that the matter will affect the financial interest." [5 C.F.R. § 2640.103(a)(ii)]

(D) How regulations concerning "appearance of a lack of impartiality," pursuant to 5 C.F.R. § 2635.502, apply to members of the Panel.

The Code of Federal Regulations at 5 C.F.R. § 2635.502(a) states that: "Where an employee knows that a particular matter involving specific parties is likely to have a direct and predictable effect on the financial interest of a member of his household, or knows that a person with whom he has a covered relationship is or represents a party to such matter, and where the person determines that the circumstances would cause a reasonable party to such matter, and where the person determines that the circumstances would cause a reasonable person with knowledge of the relevant facts to question his impartiality in the matter, the employee should not participate in the matter unless he has informed the agency designee of the appearance problem and received authorization from the agency designee." Further, § 2635.502(a)(2) states that, "An employee who is concerned that circumstances other than those specifically described

in this section would raise a question regarding his impartiality should use the process described in this section to determine whether he should or should not participate in a particular matter.”

To ascertain whether there is any appearance of a lack of impartiality, the following five questions will be posed to each member of CASAC and prospective members of the NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel with respect to the forthcoming charge for the Panel:

(a) Do you know of any reason that you might be unable to provide impartial advice on the matter to come before the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel or any reason that your impartiality in the matter might be questioned?

(b) Have you had any previous involvement with the review document(s) under consideration, *i.e.*, EPA’s 1<sup>st</sup> Draft NO<sub>x</sub> and SO<sub>x</sub> Primary Integrated Science assessment — including authorship, collaboration with the authors, or previous peer review functions? If so, please identify and describe that involvement.

(c) Have you served on previous advisory panels, committees or subcommittees (Federal or otherwise) that have addressed the topic under consideration? If so please identify those activities.

(d) Have you made any public statements (written or oral) on the issue? If so, please identify those statements.

(e) Have you made any public statements that would indicate to an observer that you have taken a position on the issue under consideration? If so, please identify those statements.

(E) How individuals were selected for the Panel.

As described in Section (B) above, the SAB Staff Office announced the formation of the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel in the *Federal Register* (71 FR 44695) on August 7, 2006, and requested nominations for recognized, national-level experts in one or more of the six scientific/technical expertise areas delineated in Section (B) above to augment the expertise of the statutory CASAC. In response to that solicitation, as well as from other sources, the SAB Staff Office identified 27 experts for the Panel’s “Short List.”

In December 2006, the SAB Staff Office published the “Short List” in the form of an “Invitation for Comments” memorandum and posted this on the Panel’s page on the SAB Web site at: [http://www.epa.gov/sab/panels/casac\\_nox\\_and\\_sox\\_primary\\_panel.htm](http://www.epa.gov/sab/panels/casac_nox_and_sox_primary_panel.htm). The purpose of the “Invitation for Comments” memo is to solicit comments from members of the public or the Agency with respect to any relevant information or other documentation that the SAB Staff Office should consider in the final selection of this Panel.

The SAB Staff Office received two (2) public comments on this Short List from individuals representing the following organizations (date):

- Clean Air Watch (January 12, 2007)
- Center for Science in the Public Interest (CSPI) (January 17, 2007)

The SAB Staff Office Director makes the final decision about who serves on the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel, based on all relevant information. This includes a review

of the member's confidential financial disclosure form (EPA Form 3110-48) and an evaluation of a lack of impartiality. For the EPA SAB Staff Office, a balanced committee or panel is characterized by inclusion of candidates who possess the necessary domains of knowledge, the relevant scientific perspectives (which, among other factors, can be influenced by work history and affiliation), and the collective breadth of experience to adequately address the general charge. Specific criteria to be used in evaluating an individual Panel member include: (a) scientific and/or technical expertise, knowledge, and experience (primary factors); (b) availability and willingness to serve; (c) absence of financial conflicts of interest; (d) absence of an appearance of a lack of impartiality; and (e) skills working in committees, subcommittees and advisory panels; and, for the Panel as a whole, (f) diversity of, and balance among, scientific expertise, viewpoints, *etc.*

*On the basis of the above-specified criteria, the CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Review Panel is as follows:*

*Members of the statutory (chartered) Clean Air Scientific Advisory Committee:*

1. **Dr. Rogene Henderson**, Lovelace Respiratory Research Institute (NM) – CASAC Chair
2. **Dr. Ellis Cowling**, North Carolina State University (NC)
3. **Dr. James D. Crapo**, National Jewish Medical and Research Center (CO)
4. **Dr. Douglas Crawford-Brown**, University of North Carolina at Chapel Hill (NC)
5. **Mr. Richard L. Poirot**, Vermont Agency of Natural Resources (VT)
6. **Dr. Armistead (Ted) Russell**, Georgia Institute of Technology (GA)
7. **Dr. Frank Speizer**, Harvard Medical School (MA)

*Additional CASAC NO<sub>x</sub> and SO<sub>x</sub> Primary Panel members:*

1. **Dr. Ed Avol**, University of Southern California (CA)
2. **Dr. John Balmes**, University of California, San Francisco (CA)
3. **Dr. Henry Gong**, University of Southern California (CA)
4. **Dr. Terry Gordon**, New York University School of Medicine (NY)
5. **Dr. Dale Hattis**, Clark University (MA)
6. **Dr. Patrick Kinney**, Columbia University, Mailman School of Public Health (NY)
7. **Dr. Steven Kleeberger**, National Institute of Environmental Health Sciences (NC)
8. **Dr. Timothy Larson**, University of Washington (WA)
9. **Dr. Kent E. Pinkerton**, University of California, Davis (CA)
10. **Dr. Edward M. Postlethwait**, University of Alabama at Birmingham (AL)
11. **Dr. Richard B. Schlesinger**, Pace University (NY)
12. **Dr. Christian Seigneur**, Atmospheric & Environmental Research, Inc. (CA)
13. **Dr. Elizabeth A. (Lianne) Sheppard**, University of Washington (WA)
14. **Dr. George Thurston**, New York University School of Medicine (NY)
15. **Dr. James Ultman**, Pennsylvania State University (Emeritus) (PA)
16. **Dr. Ronald Wyzga**, Electric Power Research Institute (CA)

# Policy Assessment for the Review of the National Ambient Air Quality Standards for Particulate Matter

EPA-452/R-20-002  
January 2020

Policy Assessment for the Review of the National Ambient Air Quality Standards for  
Particulate Matter

U.S. Environmental Protection Agency  
Office of Air Quality Planning and Standards  
Health and Environmental Impacts Division  
Research Triangle Park, NC

## **DISCLAIMER**

This Policy Assessment has been prepared by staff in the U.S. Environmental Protection Agency's (EPA) Office of Air Quality Planning and Standards. Any findings and conclusions are those of the authors and do not necessarily reflect the views of the EPA. Questions or comments related to this document should be addressed to Dr. Scott Jenkins, U.S. Environmental Protection Agency, Office of Air Quality Planning and Standards, C539-06, Research Triangle Park, North Carolina 27711 (email: [jenkins.scott@epa.gov](mailto:jenkins.scott@epa.gov)).

## TABLE OF CONTENTS

LIST OF APPENDICES .....	iii
LIST OF TABLES .....	iv
LIST OF FIGURES .....	v
LIST OF ACRONYMS AND ABBREVIATIONS .....	ix
<b>1 INTRODUCTION .....</b>	<b>1-1</b>
1.1 Purpose .....	1-1
1.2 Legislative Requirements .....	1-3
1.3 History of Reviews of the PM NAAQS.....	1-5
1.3.1 Reviews Completed in 1971 and 1987.....	1-7
1.3.2 Review Completed in 1997.....	1-7
1.3.3 Review Completed in 2006.....	1-9
1.3.4 Review Completed in 2012.....	1-11
1.4 Current Review of the PM NAAQS .....	1-11
References .....	1-16
<b>2 PM AIR QUALITY .....</b>	<b>2-1</b>
2.1 Distribution of Particle Size in Ambient Air .....	2-1
2.1.1 Sources of PM Emissions.....	2-3
2.2 Ambient PM Monitoring Methods and Networks .....	2-14
2.2.1 Total Suspended Particulates (TSP) Sampling.....	2-15
2.2.2 PM <sub>10</sub> Monitoring .....	2-16

PA	Policy Assessment
PM	Particulate matter
PM <sub>2.5</sub>	<p>In general terms, particulate matter with an aerodynamic diameter less than or equal to a nominal 2.5 µm; a measurement of fine particles</p> <p>In regulatory terms, particles with an upper 50% cut-point of 2.5 µm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) and a penetration curve as measured by a reference method based on Appendix L of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53, by an equivalent method designated in accordance with 40 CFR Part 53, or by an approved regional method designated in accordance with Appendix C of 40 CFR Part 58</p>
PM <sub>10</sub>	<p>In general terms, particulate matter with an aerodynamic diameter less than or equal to a nominal 10 µm; a measurement of thoracic particles (i.e., that subset of inhalable particles thought small enough to penetrate beyond the larynx into the thoracic region of the respiratory tract.</p> <p>In regulatory terms, particles with an upper 50% cut-point of 10 ± 0.5 µm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) and a penetration curve as measured by a reference method based on Appendix J of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53, or by an equivalent method designated in accordance with 40 CFR Part 53</p>
PM <sub>10-2.5</sub>	<p>In general terms, particulate matter with an aerodynamic diameter less than or equal to a nominal 10 µm and greater than a nominal 2.5 µm; a measurement of thoracic particles or the coarse fraction of PM<sub>10</sub></p> <p>In regulatory terms, particles with an upper 50% cut-point of 10 µm aerodynamic diameter and a lower 50% cut-point of 2.5 µm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) as measured by a reference method based on Appendix O of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53, or by an equivalent method designated in accordance with 40 CFR Part 53</p>

PRB	Policy relevant background
QA	Quality assurance
QMP	Quality Management Plan
REA	Risk and Exposure Assessment
RIA	Regulatory impact analysis
S	Sulfur
SES	Socioeconomic status
SIP	State Implementation Plan
SLAMS	State and Local Air Monitoring Stations
SO <sub>2</sub>	Sulfur dioxide
SO <sub>x</sub>	Sulfur oxides
SOPM	Secondary Organic Particulate Matter
STN	Speciation Trends Network
TAD	Technical Assistance Document
TRIM	Total Risk Integrated Methodology
TSP	Total Suspended Particles
UFP	Ultrafine Particles: Generally considered as particulates with a diameter less than or equal to 0.1 µm, typically based on physical size, thermal diffusivity or electrical mobility
UFVA	Urban-Focused Visibility Assessment
VAQ	Visual air quality
VOC	Volatile organic compound
WHO	World Health Organization
WREA	Welfare Risk and Exposure Assessment

# 1 INTRODUCTION

This document, *Policy Assessment for the Review of the National Ambient Air Quality Standards for Particulate Matter* (hereafter referred to as the PA), presents the policy assessment for the U.S. Environmental Protection Agency's (EPA's) current review of the national ambient air quality standards (NAAQS) for particulate matter (PM). The overall plan for this review was presented in the *Integrated Review Plan for the National Ambient Air Quality Standards for Particulate Matter* (IRP; U.S. EPA, 2016). The IRP also identified key policy-relevant issues to be addressed in this review and discussed the key documents that generally inform NAAQS reviews, including an Integrated Science Assessment (ISA) and a PA.

This document is organized into five chapters. Chapter 1 presents introductory information on the purpose of the PA, legislative requirements for reviews of the NAAQS, an overview of the history of the PM NAAQS, including background information on prior reviews, and a summary of the progress to date for the current review. Chapter 2 provides an overview of the available information on PM-related emissions, atmospheric chemistry, monitoring and air quality. Chapters 3 and 4 focus on policy-relevant aspects of the currently available health effects evidence and exposure/risk information, identifying and summarizing key considerations related to this review of the primary standards for PM<sub>2.5</sub> and PM<sub>10</sub>, respectively. Chapter 5 focuses on policy-relevant aspects of the currently available welfare evidence and associated quantitative analyses, identifying and summarizing key considerations related to this review of the PM secondary standards.<sup>1</sup>

## 1.1 PURPOSE

The PA evaluates the potential policy implications of the available scientific evidence, as assessed in the ISA, and the potential implications of the available air quality, exposure or risk analyses. The role of the PA is to help “bridge the gap” between the Agency's scientific assessments and quantitative technical analyses, and the judgments required of the Administrator in determining whether it is appropriate to retain or revise the NAAQS.

---

<sup>1</sup> The welfare effects considered in this review include visibility impairment, climate effects, and materials effects (i.e., damage and soiling). Ecological effects associated with PM, and the adequacy of protection provided by the secondary PM standards for them, are being addressed in the separate review of the secondary NAAQS for oxides of nitrogen, oxides of sulfur and PM in recognition of the linkages between oxides of nitrogen, oxides of sulfur, and PM with respect to atmospheric chemistry and deposition, and with respect to ecological effects. Information on the current review of the secondary NAAQS for oxides of nitrogen, oxides of sulfur and PM can be found at <https://www.epa.gov/naaqs/nitrogen-dioxide-no2-and-sulfur-dioxide-so2-secondary-air-quality-standards>.

In evaluating the question of adequacy of the current standards, and whether it may be appropriate to consider alternative standards, the PA focuses on information that is most pertinent to evaluating the standards and their basic elements: indicator, averaging time, form, and level.<sup>2</sup> These elements, which together serve to define each standard, must be considered collectively in evaluating the health and welfare protection the standards afford.

The PA is also intended to facilitate advice to the Agency and recommendations to the Administrator from an independent scientific review committee, the Clean Air Scientific Advisory Committee (CASAC), as provided for in the Clean Air Act (CAA). As discussed below in section 1.2, the CASAC is to advise on subjects including the Agency's assessment of the relevant scientific information and on the adequacy of the current standards, and to make recommendations as to any revisions of the standards that may be appropriate. The EPA generally makes available to the CASAC and the public one or more drafts of the PA for CASAC review and public comment.

In this PA, we<sup>3</sup> take into account the available scientific evidence, as assessed in the *Integrated Science Assessment for Particulate Matter (Final Report)* (ISA [U.S. EPA, 2019]), and additional policy-relevant analyses of air quality and risks. Our approach to considering the available evidence and analyses in this PA has been informed by the advice received from the CASAC, based on its review of the draft IRP and the draft ISA, and also by public comment received thus far in the review. This final PA is also informed by the advice and recommendations received from the CASAC during its review of the draft PA, and also by public comments received. The final PA is intended to help the Administrator in considering the currently available scientific and technical information, and in formulating judgments regarding the adequacy of the current standards and regarding alternative standards, as appropriate.

Beyond informing the Administrator and facilitating the advice and recommendations of the CASAC, the PA is also intended to be a useful reference to all parties interested in the review of the PM NAAQS. In these roles, it is intended to serve as a source of policy-relevant information that informs the Agency's review of the NAAQS for PM, and it is written to be understandable to a broad audience.

---

<sup>2</sup> The indicator defines the chemical species or mixture to be measured in the ambient air for the purpose of determining whether an area attains the standard. The averaging time defines the period over which air quality measurements are to be averaged or otherwise analyzed. The form of a standard defines the air quality statistic that is to be compared to the level of the standard in determining whether an area attains the standard. For example, the form of the annual NAAQS for fine particulate matter is the average of annual mean concentrations for three consecutive years, while the form of the 8-hour NAAQS for carbon monoxide is the second-highest 8-hour average in a year. The level of the standard defines the air quality concentration used for that purpose.

<sup>3</sup> The terms "we," "our," and "staff" throughout this document refer to the staff in the EPA's Office of Air Quality Planning and Standards (OAQPS).

## 1.2 LEGISLATIVE REQUIREMENTS

Two sections of the Clean Air Act (CAA) govern the establishment and revision of the NAAQS. Section 108 (42 U.S.C. 7408) directs the Administrator to identify and list certain air pollutants and then to issue air quality criteria for those pollutants. The Administrator is to list those pollutants “emissions of which, in his judgment, cause or contribute to air pollution which may reasonably be anticipated to endanger public health or welfare”; “the presence of which in the ambient air results from numerous or diverse mobile or stationary sources”; and for which he “plans to issue air quality criteria...” (42 U.S.C. § 7408(a)(1)). Air quality criteria are intended to “accurately reflect the latest scientific knowledge useful in indicating the kind and extent of all identifiable effects on public health or welfare which may be expected from the presence of [a] pollutant in the ambient air...” 42 U.S.C. § 7408(a)(2).

Section 109 [42 U.S.C. 7409] directs the Administrator to propose and promulgate “primary” and “secondary” NAAQS for pollutants for which air quality criteria are issued [42 U.S.C. § 7409(a)]. Section 109(b)(1) defines primary standards as ones “the attainment and maintenance of which in the judgment of the Administrator, based on such criteria and allowing an adequate margin of safety, are requisite to protect the public health.”<sup>4</sup> Under section 109(b)(2), a secondary standard must “specify a level of air quality the attainment and maintenance of which, in the judgment of the Administrator, based on such criteria, is requisite to protect the public welfare from any known or anticipated adverse effects associated with the presence of [the] pollutant in the ambient air.”<sup>5</sup>

In setting primary and secondary standards that are “requisite” to protect public health and welfare, respectively, as provided in section 109(b), the EPA’s task is to establish standards that are neither more nor less stringent than necessary. In so doing, the EPA may not consider the costs of implementing the standards. See generally, *Whitman v. American Trucking Associations*, 531 U.S. 457, 465-472, 475-76 (2001). Likewise, “[a]ttainability and technological feasibility are not relevant considerations in the promulgation of national ambient air quality standards.” *American Petroleum Institute v. Costle*, 665 F.2d 1176, 1185 (D.C. Cir. 1981). At the same time, courts have clarified the EPA may consider “relative proximity to peak background ... concentrations” as a factor in deciding how to revise the NAAQS in the context of considering

---

<sup>4</sup> The legislative history of section 109 indicates that a primary standard is to be set at “the maximum permissible ambient air level . . . which will protect the health of any [sensitive] group of the population,” and that for this purpose “reference should be made to a representative sample of persons comprising the sensitive group rather than to a single person in such a group.” S. Rep. No. 91-1196, 91st Cong., 2d Sess. 10 (1970).

<sup>5</sup> Under CAA section 302(h) (42 U.S.C. § 7602(h)), effects on welfare include, but are not limited to, “effects on soils, water, crops, vegetation, manmade materials, animals, wildlife, weather, visibility, and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being.”

standard levels within the range of reasonable values supported by the air quality criteria and judgments of the Administrator. *American Trucking Associations, Inc. v. EPA*, 283 F.3d 355, 379 (D.C. Cir. 2002).

The requirement that primary standards provide an adequate margin of safety was intended to address uncertainties associated with inconclusive scientific and technical information available at the time of standard setting. It was also intended to provide a reasonable degree of protection against hazards that research has not yet identified. See *Lead Industries Association v. EPA*, 647 F.2d 1130, 1154 (D.C. Cir 1980), *cert. denied*, 449 U.S. 1042 (1980); *American Petroleum Institute v. Costle*, 665 F.2d at 1186 (D.C. Cir. 1981), *cert. denied*, 455 U.S. 1034 (1982); *Coalition of Battery Recyclers Ass'n v. EPA*, 604 F.3d 613, 617-18 (D.C. Cir. 2010); *Mississippi v. EPA*, 744 F.3d 1334, 1353 (D.C. Cir. 2013). Both kinds of uncertainties are components of the risk associated with pollution at levels below those at which human health effects can be said to occur with reasonable scientific certainty. Thus, in selecting primary standards that include an adequate margin of safety, the Administrator is seeking not only to prevent pollution levels that have been demonstrated to be harmful but also to prevent lower pollutant levels that may pose an unacceptable risk of harm, even if the risk is not precisely identified as to nature or degree. The CAA does not require the Administrator to establish a primary NAAQS at a zero-risk level or at background concentration levels, see *Lead Industries v. EPA*, 647 F.2d at 1156 n.51, *Mississippi v. EPA*, 744 F.3d at 1351, but rather at a level that reduces risk sufficiently so as to protect public health with an adequate margin of safety.

In addressing the requirement for an adequate margin of safety, the EPA considers such factors as the nature and severity of the health effects involved, the size of the sensitive population(s), and the kind and degree of uncertainties. The selection of any particular approach to providing an adequate margin of safety is a policy choice left specifically to the Administrator's judgment. See *Lead Industries Association v. EPA*, 647 F.2d at 1161-62; *Mississippi v. EPA*, 744 F.3d at 1353.

Section 109(d)(1) of the Act requires a review be completed every five years and, if appropriate, revision of existing air quality criteria to reflect advances in scientific knowledge on the effects of the pollutant on public health and welfare. Under the same provision, the EPA is also to review every five years and, if appropriate, revise the NAAQS, based on the revised air quality criteria.<sup>6</sup>

Section 109(d)(2) addresses the appointment and advisory functions of an independent scientific review committee. Section 109(d)(2)(A) requires the Administrator to appoint this

---

<sup>6</sup> This section of the Act requires the Administrator to complete these reviews and make any revisions that may be appropriate "at five-year intervals."

committee, which is to be composed of “seven members including at least one member of the National Academy of Sciences, one physician, and one person representing State air pollution control agencies.” Section 109(d)(2)(B) provides that the independent scientific review committee “shall complete a review of the criteria...and the national primary and secondary ambient air quality standards...and shall recommend to the Administrator any new...standards and revisions of existing criteria and standards as may be appropriate....” Since the early 1980s, this independent review function has been performed by the Clean Air Scientific Advisory Committee (CASAC) of the EPA’s Science Advisory Board. A number of other advisory functions are also identified for the committee by section 109(d)(2)(C), which reads:

Such committee shall also (i) advise the Administrator of areas in which additional knowledge is required to appraise the adequacy and basis of existing, new, or revised national ambient air quality standards, (ii) describe the research efforts necessary to provide the required information, (iii) advise the Administrator on the relative contribution to air pollution concentrations of natural as well as anthropogenic activity, and (iv) advise the Administrator of any adverse public health, welfare, social, economic, or energy effects which may result from various strategies for attainment and maintenance of such national ambient air quality standards.

As previously noted, the Supreme Court has held that section 109(b) “unambiguously bars cost considerations from the NAAQS-setting process” (*Whitman v. Am. Trucking Associations*, 531 U.S. 457, 471 [2001]). Accordingly, while some of these issues regarding which Congress has directed the CASAC to advise the Administrator are ones that are relevant to the standard setting process, others are not. Issues that are not relevant to standard setting may be relevant to implementation of the NAAQS once they are established.<sup>7</sup>

### **1.3 HISTORY OF REVIEWS OF THE PM NAAQS**

This section summarizes the PM NAAQS that have been promulgated in past reviews (Table 1-1). Each of these reviews is discussed briefly below.

---

<sup>7</sup> Some aspects of CASAC advice may not be relevant to EPA’s process of setting primary and secondary standards that are requisite to protect public health and welfare. Indeed, were EPA to consider costs of implementation when reviewing and revising the standards “it would be grounds for vacating the NAAQS.” *Whitman*, 531 U.S. at 471 n.4. At the same time, the Clean Air Act directs CASAC to provide advice on “any adverse public health, welfare, social, economic, or energy effects which may result from various strategies for attainment and maintenance” of the NAAQS to the Administrator under section 109(d)(2)(C)(iv). In *Whitman*, the Court clarified that most of that advice would be relevant to implementation but not standard setting, as it “enable[s] the Administrator to assist the States in carrying out their statutory role as primary *implementers* of the NAAQS.” *Id.* at 470 (emphasis in original). However, the Court also noted that CASAC’s “advice concerning certain aspects of ‘adverse public health ... effects’ from various attainment strategies is unquestionably pertinent” to the NAAQS rulemaking record and relevant to the standard setting process. *Id.* at 470 n.2.

**Table 1-1. Summary of NAAQS promulgated for particulate matter 1971-2012.**

Review Completed	Indicator	Averaging Time	Level	Form
1971	Total Suspended Particles (TSP)	24-hour	260 µg/m <sup>3</sup> (primary) 150 µg/m <sup>3</sup> (secondary)	Not to be exceeded more than once per year
		Annual	75 µg/m <sup>3</sup> (primary) 60 µg/m <sup>3</sup> (secondary)	Annual geometric mean
1987	PM <sub>10</sub>	24-hour	150 µg/m <sup>3</sup>	Not to be exceeded more than once per year on average over a 3-year period
		Annual	50 µg/m <sup>3</sup>	Annual arithmetic mean, averaged over 3 years
1997	PM <sub>2.5</sub>	24-hour	65 µg/m <sup>3</sup>	98 <sup>th</sup> percentile, averaged over 3 years
		Annual	15.0 µg/m <sup>3</sup>	Annual arithmetic mean, averaged over 3 years <sup>a</sup>
	PM <sub>10</sub>	24-hour	150 µg/m <sup>3</sup>	99 <sup>th</sup> percentile, averaged over 3 years <sup>b</sup>
		Annual	50 µg/m <sup>3</sup>	Annual arithmetic mean, averaged over 3 years
2006	PM <sub>2.5</sub>	24-hour	35 µg/m <sup>3</sup>	98 <sup>th</sup> percentile, averaged over 3 years
		Annual	15.0 µg/m <sup>3</sup>	Annual arithmetic mean, averaged over 3 years <sup>c</sup>
	PM <sub>10</sub>	24-hour <sup>d</sup>	150 µg/m <sup>3</sup>	Not to be exceed more than once per year on average over a 3-year period
2012	PM <sub>2.5</sub>	24-hour	35 µg/m <sup>3</sup>	98 <sup>th</sup> percentile, averaged over 3 years
		Annual	12.0 µg/m <sup>3</sup> (primary) 15.0 µg/m <sup>3</sup> (secondary)	Annual mean, averaged over 3 years <sup>e</sup>
	PM <sub>10</sub>	24-hour	150 µg/m <sup>3</sup>	Not to be exceeded more than once per year on average over 3 years
<p>Note: When not specified, primary and secondary standards are identical.</p> <p><sup>a</sup> The level of the 1997 annual PM<sub>2.5</sub> standard was to be compared to measurements made at the community-oriented monitoring site recording the highest concentration or, if specific constraints were met, measurements from multiple community-oriented monitoring sites could be averaged (i.e., “spatial averaging”) (62 FR 38652, July 18, 1997).</p> <p><sup>b</sup> When the 1997 standards were vacated (see below), the form of the 1987 standards remained in place (i.e., not to be exceeded more than once per year on average over a 3-year period).</p> <p><sup>c</sup> The EPA tightened the constraints on the spatial averaging criteria by further limiting the conditions under which some areas may average measurements from multiple community-oriented monitors to determine compliance (71 FR 61144, October 17, 2006).</p> <p><sup>d</sup> The EPA revoked the annual PM<sub>10</sub> NAAQS in 2006 (71 FR 61144, October 17, 2006).</p> <p><sup>e</sup> In the 2012 decision, the EPA eliminated the option for spatial averaging (78 FR 3086, January 15, 2013).</p>				

### 1.3.1 Reviews Completed in 1971 and 1987

The EPA first established NAAQS for PM in 1971 (36 FR 8186, April 30, 1971), based on the original Air Quality Criteria Document (AQCD) (DHEW, 1969).<sup>8</sup> The federal reference method (FRM) specified for determining attainment of the original standards was the high-volume sampler, which collects PM up to a nominal size of 25 to 45 micrometers ( $\mu\text{m}$ ) (referred to as total suspended particulates or TSP). The primary standards were set at  $260 \mu\text{g}/\text{m}^3$ , 24-hour average, not to be exceeded more than once per year, and  $75 \mu\text{g}/\text{m}^3$ , annual geometric mean. The secondary standards were set at  $150 \mu\text{g}/\text{m}^3$ , 24-hour average, not to be exceeded more than once per year, and  $60 \mu\text{g}/\text{m}^3$ , annual geometric mean.

In October 1979 (44 FR 56730, October 2, 1979), the EPA announced the first periodic review of the air quality criteria and NAAQS for PM. Revised primary and secondary standards were promulgated in 1987 (52 FR 24634, July 1, 1987). In the 1987 decision, the EPA changed the indicator for particles from TSP to  $\text{PM}_{10}$ , in order to focus on the subset of inhalable particles small enough to penetrate to the thoracic region of the respiratory tract (including the tracheobronchial and alveolar regions), referred to as thoracic particles.<sup>9</sup> The level of the 24-hour standards (primary and secondary) was set at  $150 \mu\text{g}/\text{m}^3$ , and the form was one expected exceedance per year, on average over three years. The level of the annual standards (primary and secondary) was set at  $50 \mu\text{g}/\text{m}^3$ , and the form was annual arithmetic mean, averaged over three years.

### 1.3.2 Review Completed in 1997

In April 1994, the EPA announced its plans for the second periodic review of the air quality criteria and NAAQS for PM, and in 1997 the EPA promulgated revisions to the NAAQS (62 FR 38652, July 18, 1997). In the 1997 decision, the EPA determined that the fine and coarse fractions of  $\text{PM}_{10}$  should be considered separately. This determination was based on evidence that serious health effects were associated with short- and long-term exposures to fine particles in areas that met the existing  $\text{PM}_{10}$  standards. The EPA added new standards, using  $\text{PM}_{2.5}$  as the indicator for fine particles (with  $\text{PM}_{2.5}$  referring to particles with a nominal mean aerodynamic diameter less than or equal to  $2.5 \mu\text{m}$ ). The new primary standards were as follows: (1) an annual standard with a level of  $15.0 \mu\text{g}/\text{m}^3$ , based on the 3-year average of annual arithmetic mean

---

<sup>8</sup> Prior to the review initiated in 2007 (see below), the AQCD provided the scientific foundation (i.e., the air quality criteria) for the NAAQS. Beginning in that review, the Integrated Science Assessment (ISA) has replaced the AQCD.

<sup>9</sup>  $\text{PM}_{10}$  refers to particles with a nominal mean aerodynamic diameter less than or equal to  $10 \mu\text{m}$ . More specifically,  $10 \mu\text{m}$  is the aerodynamic diameter for which the efficiency of particle collection is 50 percent.

PM<sub>2.5</sub> concentrations from single or multiple community-oriented monitors;<sup>10</sup> and (2) a 24-hour standard with a level of 65 µg/m<sup>3</sup>, based on the 3-year average of the 98<sup>th</sup> percentile of 24-hour PM<sub>2.5</sub> concentrations at each monitor within an area. Also, the EPA established a new reference method for the measurement of PM<sub>2.5</sub> in the ambient air and adopted rules for determining attainment of the new standards. To continue to address the health effects of the coarse fraction of PM<sub>10</sub> (referred to as thoracic coarse particles or PM<sub>10-2.5</sub>; generally including particles with a nominal mean aerodynamic diameter greater than 2.5 µm and less than or equal to 10 µm), the EPA retained the annual primary PM<sub>10</sub> standard and revised the form of the 24-hour primary PM<sub>10</sub> standard to be based on the 99<sup>th</sup> percentile of 24-hour PM<sub>10</sub> concentrations at each monitor in an area. The EPA revised the secondary standards by setting them equal in all respects to the newly established primary standards.

Following promulgation of the 1997 PM NAAQS, petitions for review were filed by several parties, addressing a broad range of issues. In May 1999, the U.S. Court of Appeals for the District of Columbia Circuit (D.C. Circuit) upheld the EPA's decision to establish fine particle standards, holding that "the growing empirical evidence demonstrating a relationship between fine particle pollution and adverse health effects amply justifies establishment of new fine particle standards." *American Trucking Associations v. EPA*, 175 F. 3d at 1027, 1055-56 (D.C. Cir. 1999). The D.C. Circuit also found "ample support" for the EPA's decision to regulate coarse particle pollution, but vacated the 1997 PM<sub>10</sub> standards, concluding that the EPA had not provided a reasonable explanation justifying use of PM<sub>10</sub> as an indicator for coarse particles. *American Trucking Associations v. EPA*, 175 F. 3d at 1054-55. Pursuant to the D.C. Circuit's decision, the EPA removed the vacated 1997 PM<sub>10</sub> standards, and the pre-existing 1987 PM<sub>10</sub> standards remained in place (65 FR 80776, December 22, 2000). The D.C. Circuit also upheld the EPA's determination not to establish more stringent secondary standards for fine particles to address effects on visibility. *American Trucking Associations v. EPA*, 175 F. 3d at 1027.

The D.C. Circuit also addressed more general issues related to the NAAQS, including issues related to the consideration of costs in setting NAAQS and the EPA's approach to establishing the levels of NAAQS. Regarding the cost issue, the court reaffirmed prior rulings holding that in setting NAAQS the EPA is "not permitted to consider the cost of implementing those standards." *American Trucking Associations v. EPA*, 175 F. 3d at 1040-41. Regarding the

---

<sup>10</sup> The 1997 annual PM<sub>2.5</sub> standard was to be compared with measurements made at the community-oriented monitoring site recording the highest concentration or, if specific constraints were met, measurements from multiple community-oriented monitoring sites could be averaged (i.e., "spatial averaging"). In the last review (completed in 2012) the EPA replaced the term "community-oriented" monitor with the term "area-wide" monitor. Area-wide monitors are those sited at the neighborhood scale or larger, as well as those monitors sited at micro- or middle-scales that are representative of many such locations in the same CBSA (78 FR 3236, January 15, 2013).

levels of NAAQS, the court held that the EPA's approach to establishing the level of the standards in 1997 (i.e., both for PM and for the ozone NAAQS promulgated on the same day) effected "an unconstitutional delegation of legislative authority." *American Trucking Associations v. EPA*, 175 F. 3d at 1034-40. Although the court stated that "the factors EPA uses in determining the degree of public health concern associated with different levels of ozone and PM are reasonable," it remanded the rule to the EPA, stating that when the EPA considers these factors for potential non-threshold pollutants "what EPA lacks is any determinate criterion for drawing lines" to determine where the standards should be set.

The D.C. Circuit's holding on the cost and constitutional issues were appealed to the United States Supreme Court. In February 2001, the Supreme Court issued a unanimous decision upholding the EPA's position on both the cost and constitutional issues. *Whitman v. American Trucking Associations*, 531 U.S. 457, 464, 475-76. On the constitutional issue, the Court held that the statutory requirement that NAAQS be "requisite" to protect public health with an adequate margin of safety sufficiently guided the EPA's discretion, affirming the EPA's approach of setting standards that are neither more nor less stringent than necessary.

The Supreme Court remanded the case to the Court of Appeals for resolution of any remaining issues that had not been addressed in that court's earlier rulings. *Id.* at 475-76. In a March 2002 decision, the Court of Appeals rejected all remaining challenges to the standards, holding that the EPA's PM<sub>2.5</sub> standards were reasonably supported by the administrative record and were not "arbitrary and capricious" *American Trucking Associations v. EPA*, 283 F. 3d 355, 369-72 (D.C. Cir. 2002).

### **1.3.3 Review Completed in 2006**

In October 1997, the EPA published its plans for the third periodic review of the air quality criteria and NAAQS for PM (62 FR 55201, October 23, 1997). After the CASAC and public review of several drafts, the EPA's NCEA finalized the AQCD in October 2004 (U.S. EPA, 2004a, U.S. EPA, 2004b). The EPA's OAQPS finalized a Risk Assessment and Staff Paper in December 2005 (Abt Associates, 2005, U.S. EPA, 2005).<sup>11</sup> On December 20, 2005, the EPA announced its proposed decision to revise the NAAQS for PM and solicited public comment on a broad range of options (71 FR 2620, January 17, 2006). On September 21, 2006, the EPA announced its final decisions to revise the primary and secondary NAAQS for PM to provide increased protection of public health and welfare, respectively (71 FR 61144, October 17, 2006).

---

<sup>11</sup> Prior to the review initiated in 2007, the Staff Paper presented the EPA staff's considerations and conclusions regarding the adequacy of existing NAAQS and, when appropriate, the potential alternative standards that could be supported by the evidence and information. More recent reviews present this information in the Policy Assessment.

With regard to the primary and secondary standards for fine particles, the EPA revised the level of the 24-hour  $PM_{2.5}$  standards to  $35 \mu g/m^3$ , retained the level of the annual  $PM_{2.5}$  standards at  $15.0 \mu g/m^3$ , and revised the form of the annual  $PM_{2.5}$  standards by narrowing the constraints on the optional use of spatial averaging. With regard to the primary and secondary standards for  $PM_{10}$ , the EPA retained the 24-hour standards, with levels at  $150 \mu g/m^3$ , and revoked the annual standards.<sup>12</sup> The Administrator judged that the available evidence generally did not suggest a link between long-term exposure to existing ambient levels of coarse particles and health or welfare effects. In addition, a new reference method was added for the measurement of  $PM_{10-2.5}$  in the ambient air in order to provide a basis for approving federal equivalent methods (FEMs) and to promote the gathering of scientific data to support future reviews of the PM NAAQS.

Several parties filed petitions for review following promulgation of the revised PM NAAQS in 2006. These petitions addressed the following issues: (1) selecting the level of the primary annual  $PM_{2.5}$  standard; (2) retaining  $PM_{10}$  as the indicator of a standard for thoracic coarse particles, retaining the level and form of the 24-hour  $PM_{10}$  standard, and revoking the  $PM_{10}$  annual standard; and (3) setting the secondary  $PM_{2.5}$  standards identical to the primary standards. On February 24, 2009, the U.S. Court of Appeals for the District of Columbia Circuit issued its opinion in the case *American Farm Bureau Federation v. EPA*, 559 F. 3d 512 (D.C. Cir. 2009). The court remanded the primary annual  $PM_{2.5}$  NAAQS to the EPA because the Agency failed to adequately explain why the standards provided the requisite protection from both short- and long-term exposures to fine particles, including protection for at-risk populations. *American Farm Bureau Federation v. EPA*, 559 F. 3d 512, 520-27 (D.C. Cir. 2009). With regard to the standards for  $PM_{10}$ , the court upheld the EPA's decisions to retain the 24-hour  $PM_{10}$  standard to provide protection from thoracic coarse particle exposures and to revoke the annual  $PM_{10}$  standard. *American Farm Bureau Federation*, 559 F. 2d at 533-38. With regard to the secondary  $PM_{2.5}$  standards, the court remanded the standards to the EPA because the Agency failed to adequately explain why setting the secondary PM standards identical to the primary standards provided the required protection for public welfare, including protection from visibility impairment. *American Farm Bureau Federation*, 559 F. 2d at 528-32. The EPA responded to the

---

<sup>12</sup> In the 2006 proposal, the EPA proposed to revise the 24-hour  $PM_{10}$  standard in part by establishing a new  $PM_{10-2.5}$  indicator for thoracic coarse particles (i.e., particles generally between 2.5 and 10  $\mu m$  in diameter). The EPA proposed to include any ambient mix of  $PM_{10-2.5}$  that was dominated by resuspended dust from high density traffic on paved roads and by PM from industrial sources and construction sources. The EPA proposed to exclude any ambient mix of  $PM_{10-2.5}$  that was dominated by rural windblown dust and soils and by PM generated from agricultural and mining sources. In the final decision, the existing  $PM_{10}$  standard was retained, in part due to an "inability...to effectively and precisely identify which ambient mixes are included in the [ $PM_{10-2.5}$ ] indicator and which are not" (71 FR 61197, October 17, 2006).

court's remands as part of the next review of the PM NAAQS, which was initiated in 2007 (discussed below).

### **1.3.4 Review Completed in 2012**

In June 2007, the EPA initiated the fourth periodic review of the air quality criteria and the PM NAAQS by issuing a call for information in the *Federal Register* (72 FR 35462, June 28, 2007). Based on the NAAQS review process, as revised in 2008 and again in 2009,<sup>13</sup> the EPA held science/policy issue workshops on the primary and secondary PM NAAQS (72 FR 34003, June 20, 2007; 72 FR 34005, June 20, 2007), and prepared and released the planning and assessment documents that comprise the review process (i.e., IRP (U.S. EPA, 2008), ISA (U.S. EPA, 2009a), REA planning documents for health and welfare (U.S. EPA, 2009b, U.S. EPA, 2009c), a quantitative health risk assessment (U.S. EPA, 2010a) and an urban-focused visibility assessment (U.S. EPA, 2010b), and PA (U.S. EPA, 2011)). In June 2012, the EPA announced its proposed decision to revise the NAAQS for PM (77 FR 38890, June 29, 2012).

In December 2012, the EPA announced its final decisions to revise the primary NAAQS for PM to provide increased protection of public health (78 FR 3086, January 15, 2013). With regard to primary standards for PM<sub>2.5</sub>, the EPA revised the level of the annual PM<sub>2.5</sub> standard<sup>14</sup> to 12.0 µg/m<sup>3</sup> and retained the 24-hour PM<sub>2.5</sub> standard, with its level of 35 µg/m<sup>3</sup>. For the primary PM<sub>10</sub> standard, the EPA retained the 24-hour standard to continue to provide protection against effects associated with short-term exposure to thoracic coarse particles (i.e., PM<sub>10-2.5</sub>). With regard to the secondary PM standards, the EPA generally retained the 24-hour and annual PM<sub>2.5</sub> standards<sup>15</sup> and the 24-hour PM<sub>10</sub> standard to address visibility and non-visibility welfare effects.

As with previous reviews, petitioners challenged the EPA's final rule. Petitioners argued that the EPA acted unreasonably in revising the level and form of the annual standard and in amending the monitoring network provisions. On judicial review, the revised standards and monitoring requirements were upheld in all respects. *NAM v EPA*, 750 F.3d 921 (D.C. Cir. 2014).

## **1.4 CURRENT REVIEW OF THE PM NAAQS**

In December 2014, the EPA announced the initiation of the current periodic review of the air quality criteria for PM and of the PM<sub>2.5</sub> and PM<sub>10</sub> NAAQS and issued a call for information

---

<sup>13</sup> The history of the NAAQS review process, including revisions to the process, is discussed at <http://www3.epa.gov/ttn/naaqs/review2.html>.

<sup>14</sup> The EPA also eliminated the option for spatial averaging.

<sup>15</sup> Consistent with the primary standard, the EPA eliminated the option for spatial averaging with the annual standard.

in the *Federal Register* (79 FR 71764, December 3, 2014). On February 9 to 11, 2015, the EPA's NCEA and OAQPS held a public workshop to inform the planning for the current review of the PM NAAQS (announced in 79 FR 71764, December 3, 2014). Workshop participants, including a wide range of external experts as well as EPA staff representing a variety of areas of expertise (e.g., epidemiology, human and animal toxicology, risk/exposure analysis, atmospheric science, visibility impairment, climate effects), were asked to highlight significant new and emerging PM research, and to make recommendations to the Agency regarding the design and scope of this review. This workshop provided for a public discussion of the key science and policy-relevant issues around which the EPA has structured the current review of the PM NAAQS and of the most meaningful new scientific information that would be available in this review to inform our understanding of these issues.

The input received at the workshop guided the EPA staff in developing a draft IRP, which was reviewed by the CASAC Particulate Matter Panel and discussed on public teleconferences held in May 2016 (81 FR 13362, March 14, 2016) and August 2016 (81 FR 39043, June 15, 2016). Advice from the CASAC, supplemented by the Particulate Matter Panel, and input from the public were considered in developing the final IRP for this review (U.S. EPA, 2016). The final IRP discusses the approaches to be taken in developing key scientific, technical, and policy documents in this review and the key policy-relevant issues that will frame the EPA's consideration of whether the current primary and/or secondary NAAQS for PM should be retained or revised.

In May 2018, the Administrator issued a memorandum describing a "back-to-basics" process for reviewing the NAAQS (Pruitt, 2018). This memo announced the Agency's intention to conduct the current review of the PM NAAQS in such a manner as to ensure that any necessary revisions are finalized by December 2020. Following this memo, on October 10, 2018 the Administrator additionally announced that the role of reviewing the key science assessments developed as part of the ongoing review of the PM NAAQS (i.e., drafts of the ISA and PA) would be performed by the seven-member chartered CASAC (i.e., rather than the CASAC Particulate Matter Panel that reviewed the draft IRP).<sup>16</sup>

The EPA released the draft ISA in October 2018 (83 FR 53471, October 23, 2018). The draft ISA was reviewed by the chartered CASAC at a public meeting held in Arlington, VA in December 2018 (83 FR 55529, November 6, 2018) and was discussed on a public teleconference in March 2019 (84 FR 8523, March 8, 2019). The CASAC provided its advice on the draft ISA in a letter to the EPA Administrator dated April 11, 2019 (Cox, 2019a). In that letter, the

---

<sup>16</sup> Announcement available at: <https://www.epa.gov/newsreleases/acting-administrator-wheeler-announces-science-advisors-key-clean-air-act-committee>

CASAC's recommendations address both the draft ISA's assessment of the science for PM-related effects and the process under which this review of the PM NAAQS is being conducted.

Regarding the assessment of the evidence, the CASAC letter states that "the Draft ISA does not provide a sufficiently comprehensive, systematic assessment of the available science relevant to understanding the health impacts of exposure to particulate matter (PM)" (Cox, 2019, p. 1 of letter). The CASAC recommends that this and other limitations (i.e., "[i]nadequate evidence for altered causal determinations" and the need for a "[c]learer discussion of causality and causal biological mechanisms and pathways") be remedied in a revised ISA (Cox, 2019, p. 1 of letter). The EPA has taken steps to address these comments in the Final PM ISA (U.S. EPA, 2019). In particular, the final ISA includes additional text and a new appendix to clarify the comprehensive and systematic process employed by the EPA to develop the PM ISA. In addition, several causality determinations were re-examined and the final ISA reflects a revised causality determination for long-term ultrafine particle exposures and nervous system effects (i.e., from "likely to be causal" to "suggestive of, but not sufficient to infer, a causal relationship"). The final ISA also contains additional text to clarify the evidence for biological pathways of particular PM-related effects and the role of that evidence in causality determinations.

Among its comments on the process, the chartered CASAC recommended "that the EPA reappoint the previous CASAC PM panel (or appoint a panel with similar expertise)" (Cox, 2019a). The Agency's response to this advice was provided in a letter from the Administrator to the CASAC chair dated July 25, 2019.<sup>17</sup> As indicated in that letter, on September 13, 2019 the Administrator announced the selection of a pool of non-member subject matter experts. These experts were intended to "provide technical expertise to help CASAC ensure a rigorous and timely review of the National Ambient Air Quality Standards for particulate matter and ozone."<sup>18</sup> Input from members of this pool of experts informed the CASAC's review of the draft PA.

The EPA released the draft PA in September 2019 (84 FR 47944, September 11, 2019). The draft PA was reviewed by the chartered CASAC and discussed in October 2019 at a public meeting held in Cary, NC. Public comments were received via a separate public teleconference (84 FR 51555, September 30, 2019). A public meeting to discuss the chartered CASAC letter and response to charge questions on the draft PA was held in Cary, NC in December 2019 (84 FR 58713, November 1, 2019), and the CASAC provided its advice on the draft PA, including its

[https://yosemite.epa.gov/sab/sabproduct.nsf/0/6CBCBBC3025E13B4852583D90047B352/\\$File/EPA-CASAC-19-002\\_Response.pdf](https://yosemite.epa.gov/sab/sabproduct.nsf/0/6CBCBBC3025E13B4852583D90047B352/$File/EPA-CASAC-19-002_Response.pdf)

<sup>18</sup> Available at: <https://www.epa.gov/newsreleases/administrator-wheeler-announces-new-casac-member-pool-naaqs-subject-matter-experts>

advice on the current primary and secondary PM standards, in a letter to the EPA Administrator dated December 16, 2019 (Cox, 2019b).

With regard to the primary standards, the CASAC recommends retaining the current 24-hour PM<sub>2.5</sub> and PM<sub>10</sub> standards, but does not reach consensus on the adequacy of the current annual PM<sub>2.5</sub> standard. With regard to the secondary standards, the CASAC recommends retaining the current standards. The CASAC's advice on the primary and secondary PM standards is discussed in detail in chapters 3 (primary PM<sub>2.5</sub> standards), 4 (primary PM<sub>10</sub> standards), and 5 (secondary standards) of this final PA.

The CASAC additionally makes a number of recommendations regarding the information and analyses presented in the draft PA. Specifically, the CASAC recommends that a revised PA include (1) additional discussion of the current CASAC and NAAQS review process; (2) additional characterization of PM-related emissions, monitoring and air quality information, including uncertainties in that information; (3) additional discussion and examination of uncertainties in the PM<sub>2.5</sub> health evidence and the risk assessment; (4) updates to reflect changes in the ISA's causality determinations; and (5) additional discussion of the evidence for PM-related welfare effects, including uncertainties (Cox, 2019b, pp. 2-3 in letter). In response to the CASAC's comments, we have incorporated a number of changes into this final PA, including the following:

- (1) We have added text to Chapter 1 (see above) to clarify the process followed for this review of the PM NAAQS, including how the process has evolved since the initiation of the review.
- (2) We have added text and figures to Chapter 2 on emissions of PM and PM precursors, and we have added a section discussing uncertainty in emissions estimates. We have also added new discussion of measurement uncertainty for FRM, FEM, CSN, and IMPROVE monitors.
- (3) In Chapter 3 and Appendices B and C, we have made a number of changes:
  - a. We have reduced the emphasis on evidence for long-term ultrafine particle exposures and nervous system effects to reflect the change in the final ISA's causality determination from "likely to be causal" to "suggestive of, but not sufficient to infer, a causal relationship."
  - b. We have expanded the characterization and discussion of the evidence related to exposure measurement error, the potential confounders examined by key studies, the shapes of concentration-response functions, and the results of causal inference and quasi-experimental studies.

- c. We have expanded and clarified the discussion of uncertainties in the risk assessment,<sup>19</sup> and we have added additional air quality model performance evaluation for each of the urban study areas included in the risk assessment.
  - d. We have provided additional detail on the procedure used to derive concentration-response functions used in the risk assessment.
- (4) Throughout the document (Chapters 3, 4 and 5), we have added summaries of the CASAC advice on the PM standards, and we have expanded the discussion of data gaps and areas for future research in the health and welfare effects evidence.

---

<sup>19</sup> The CASAC's comments on the risk assessment include recommending additional analyses to quantify uncertainty in estimates of how PM<sub>2.5</sub>-related risks may change with changing ambient PM<sub>2.5</sub> concentrations (Cox, 2019b, p. 7 of consensus responses). While this final PA includes additional discussion of sources of uncertainty in the risk assessment, and additional qualitative consideration of the potential impacts of those uncertainties on risk estimates, we have not conducted additional analyses to further quantify uncertainty. This approach to addressing the CASAC's comments on the risk assessment reflects our consideration of the timeline for this review as well as the likely impact of such additional analyses on decision making.

## 2 PM AIR QUALITY

This chapter provides an overview of recent ambient air quality with respect to PM. It summarizes information on the distribution of particle size in ambient air, including discussions about size fractions and components (section 2.1), ambient monitoring of PM in the U.S. (section 2.2), ambient concentrations of PM in the U.S. (section 2.3), and background PM (section 2.4).

### 2.1 DISTRIBUTION OF PARTICLE SIZE IN AMBIENT AIR

In ambient air, PM is a mixture of substances suspended as small liquid and/or solid particles. Particle size is an important consideration for PM, as distinct health and welfare effects have been linked with exposures to particles of different sizes. Particles in the atmosphere range in size from less than 0.01 to more than 10 micrometers ( $\mu\text{m}$ ) in diameter (U.S. EPA, 2019a, section 2.2). When describing PM, subscripts are used to denote the aerodynamic diameter<sup>1</sup> of the particle size range in micrometers ( $\mu\text{m}$ ) of 50% cut points of sampling devices. The EPA defines  $\text{PM}_{2.5}$ , also referred to as fine particles, as particles with aerodynamic diameters generally less than or equal to 2.5  $\mu\text{m}$ . The size range for  $\text{PM}_{10-2.5}$ , also called coarse or thoracic coarse particles, includes those particles with aerodynamic diameters generally greater than 2.5  $\mu\text{m}$  and less than or equal to 10  $\mu\text{m}$ .  $\text{PM}_{10}$ , which is comprised of both fine and coarse fractions, includes those particles with aerodynamic diameters generally less than or equal to 10  $\mu\text{m}$ . Figure 2-1 provides perspective on these particle size fractions. In addition, ultrafine particles (UFP) are often defined as particles with a diameter of less than 0.1  $\mu\text{m}$  based on physical size, thermal diffusivity or electrical mobility (U.S. EPA, 2019a, section 2.2).

---

<sup>1</sup> Aerodynamic diameter is the size of a sphere of unit density (i.e., 1  $\text{g}/\text{cm}^3$ ) that has the same terminal settling velocity as the particle of interest (U.S. EPA, 2018, U.S. EPA, 2019a, section 4.1.1).

**Figure 2-1. Comparisons of PM<sub>2.5</sub> and PM<sub>10</sub> diameters to human hair and beach sand.**  
 (Adapted from: <https://www.epa.gov/pm-pollution/particulate-matter-pm-basics>)

Atmospheric distributions of particle size generally exhibit distinct modes that roughly align with the PM size fractions defined above. The nucleation mode is made up of freshly generated particles, formed either during combustion or by atmospheric reactions of precursor gases. The nucleation mode is especially prominent near sources like heavy traffic, industrial emissions, biomass burning, or cooking (Vu et al., 2015). While nucleation mode particles are only a minor contributor to overall ambient PM mass and surface area, they are the main contributors to ambient particle number (U.S. EPA, 2019a, section 2.2). By number, most nucleation mode particles fall into the UFP size range, though some fraction of the nucleation mode number distribution can extend above 0.1  $\mu\text{m}$  in diameter. Nucleation mode particles can grow rapidly through coagulation or uptake of gases by particle surfaces, giving rise to the accumulation mode. The accumulation mode is typically the predominant contributor to PM<sub>2.5</sub> mass and surface area, though only a minor contributor to particle number (U.S. EPA, 2019a, section 2.2). PM<sub>2.5</sub> sampling methods measure most of the accumulation mode mass, although a small fraction of particles that make up the accumulation mode are greater than 2.5  $\mu\text{m}$  in diameter. Coarse mode particles are formed by mechanical generation, and through processes like dust resuspension and sea spray formation (Whitby et al., 1972). Most coarse mode mass is captured by PM<sub>10-2.5</sub> sampling, but small fractions of coarse mode mass can be smaller than 2.5  $\mu\text{m}$  or greater than 10  $\mu\text{m}$  in diameter (U.S. EPA, 2019a, section 2.2).

Most particles are found in the lower troposphere, where they can have residence times ranging from a few hours to weeks. Particles are removed from the atmosphere by wet

deposition, such as when they are carried by rain or snow, or by dry deposition, when particles settle out of suspension due to gravity. Atmospheric lifetimes are generally longest for PM<sub>2.5</sub>, which often remains in the atmosphere for days to weeks (U.S. EPA, 2019a, Table 2-1) before being removed by wet or dry deposition. In contrast, atmospheric lifetimes for UFP and PM<sub>10-2.5</sub> are shorter. Within hours, UFP can undergo coagulation and condensation that lead to formation of larger particles in the accumulation mode, or can be removed from the atmosphere by evaporation, deposition, or reactions with other atmospheric components. PM<sub>10-2.5</sub> are also generally removed from the atmosphere within hours, through wet or dry deposition (U.S. EPA, 2019a, Table 2-1).

### **2.1.1 Sources of PM Emissions**

PM is composed of both primary (directly emitted particles) and secondary chemical components. Primary PM is derived from direct particle emissions from specific PM sources while secondary PM originates from gas-phase chemical compounds present in the atmosphere that have participated in new particle formation or condensed onto existing particles (U.S. EPA, 2019a, section 2.3). Primary particles, and gas-phase compounds contributing to secondary formation PM, are emitted from both anthropogenic and natural sources.

Anthropogenic sources of PM include both stationary and mobile sources. Stationary sources include fuel combustion for electricity production and other purposes, industrial processes, agricultural activities, and road and building construction and demolition. Mobile sources of PM include diesel- and gasoline-powered highway vehicles and other engine-driven sources (e.g., ships, aircraft, and construction and agricultural equipment). Both stationary and mobile sources directly emit primary PM to ambient air, along with secondary PM precursors (e.g., SO<sub>2</sub>) that contribute to the secondary formation of PM in the atmosphere (U.S. EPA, 2019a, section 2.3, Table 2-2).

Natural sources of PM include dust from the wind erosion of natural surfaces, sea salt, wildland fires, primary biological aerosol particles (PBAP) such as bacteria and pollen, oxidation of biogenic hydrocarbons such as isoprene and terpenes to produce secondary organic aerosol (SOA), and geogenic sources such as sulfate formed from volcanic production of SO<sub>2</sub> (U.S. EPA, 2009, section 3.3, Table 3-2). While most of the above sources release or contribute predominantly to fine aerosol, some sources including windblown dust, and sea salt also produce particles in the coarse size range (U.S. EPA, 2019a, section 2.3.3).

Generally, the sources of PM for different size fractions vary. While PM<sub>2.5</sub> in ambient air is largely emitted directly by sources such as those described above or through secondary PM formation in the atmosphere, PM<sub>10-2.5</sub> is almost entirely from primary sources (i.e., directly emitted) and is produced by surface abrasion or by suspension of sea spray or biological

materials such as microorganisms, pollen, and plant and insect debris (U.S. EPA, 2019a, section 2.3.2.1).

In sections 2.1.1.1 and 2.1.1.2 below, we describe the most recently available information on sources contributing to PM<sub>2.5</sub> and PM<sub>10-2.5</sub> emissions into ambient air, respectively, based on the U.S. EPA 2014 National Emissions Inventory (NEI).<sup>2</sup> In section 2.1.1.3, we describe information on sources contributing to emissions of PM components and precursor gases.

#### **2.1.1.1 Sources Contributing to Primary PM<sub>2.5</sub> Emissions**

The National Emissions Inventory (NEI) is a comprehensive and detailed estimate of air emissions of criteria pollutants, criteria precursors, and hazardous air pollutants from a comprehensive set of air emissions sources, including point sources (electric generating units, boilers, etc.), nonpoint (or area) sources (oil & gas, residential wood combustion, and many other dispersed sources), mobiles sources, and events (large fires). There are over 3,000 sources for which the NEI is developed. The NEI is released every three years based primarily upon data provided by State, Local, and Tribal air agencies for sources in their jurisdictions and supplemented by data developed by the U.S. EPA. The NEI is built using the Emissions Inventory System (EIS) first to collect the data from State, Local, and Tribal air agencies and then to blend that data with other data sources.

Based on the 2014 NEI, approximately 5.4 million tons/year of PM<sub>2.5</sub> were estimated to be directly emitted to the atmosphere from a number of source sectors in the U.S. This total excludes sources that are not a part of the NEI (e.g., windblown dust, geogenic sources). As shown in Figure 2-2, nearly half of the total primary PM<sub>2.5</sub> emissions nationally are contributed by the dust and fire sectors together. Dust includes agricultural, construction, and road dust. Of these, agricultural dust and road dust in sum make the greatest contributions to PM<sub>2.5</sub> emissions nationally. Fires include wildfires, prescribed fires, and agricultural fires, with wildfires and prescribed fires accounting for most of the fire-related primary PM<sub>2.5</sub> emissions nationally (U.S. EPA, 2019a, section 2.3.1.1). Other lesser-contributing anthropogenic sources of PM<sub>2.5</sub> emissions nationally include stationary fuel combustion and agriculture sources (e.g., agricultural tilling).

---

<sup>2</sup> These sections do not provide a comprehensive list of all sources, nor does it provide estimates of emission rates or emission factors for all source categories. Individual subsectors of source types were aggregated up to a sector level as used in Figure 2-2 and Figure 2-4. More information about the sectors and subsectors can be found as a part of the 2014 NEI available from [https://www.epa.gov/sites/production/files/2018-07/documents/nei2014v2\\_tsd\\_05jul2018.pdf](https://www.epa.gov/sites/production/files/2018-07/documents/nei2014v2_tsd_05jul2018.pdf).

**Figure 2-2. Percent contribution of PM<sub>2.5</sub> emissions by national source sectors.** (Source: 2014 NEI)

The relative contributions of specific sources to annual emissions of primary PM<sub>2.5</sub> can vary from location to location, with a notable difference in contributions of sources of PM<sub>2.5</sub> emissions in urban areas compared to national emissions. For example, the ISA illustrates this variation of primary PM<sub>2.5</sub> emissions with data from five urban counties in the U.S. (U.S. EPA, 2019a, Figure 2-3).<sup>3</sup> Across the majority of these urban areas, the largest PM<sub>2.5</sub>-emitting sectors are mobile sources and fuel combustion. This is in contrast to fires, which account for the largest fraction of primary emissions nationally but make much smaller contributions in many urban counties (U.S. EPA, 2019a, section 2.3.1.2, Figure 2-3). While primary PM<sub>2.5</sub> from mobile sources are a dominant contributor in some urban areas, accounting for an estimated 13 to 30% of the total primary PM<sub>2.5</sub> emissions, mobile sources contribute only about 7% to total primary PM<sub>2.5</sub> emissions nationally as shown in Figure 2-2.

Another way to look at the emissions data shown in Figure 2-2 is by county. Figure 2-4 presents county-based total PM<sub>2.5</sub> emissions divided by the area of the county to normalize for

<sup>3</sup> The five counties included in the ISA analysis include Queens County, NY, Philadelphia County, PA, Los Angeles County, CA, Sacramento County, CA, and Maricopa County (Phoenix), AZ (U.S. EPA, 2019a, section 2.3.1.2).

differences in county size. This “emissions density” map highlights regions of the country with the strongest emitting sectors for PM<sub>2.5</sub>.

**Figure 2-3. 2014 NEI PM<sub>2.5</sub> Emissions Density Map, tons per square mile**

#### **2.1.1.2 Sources Contributing to Primary PM<sub>10</sub> Emissions**

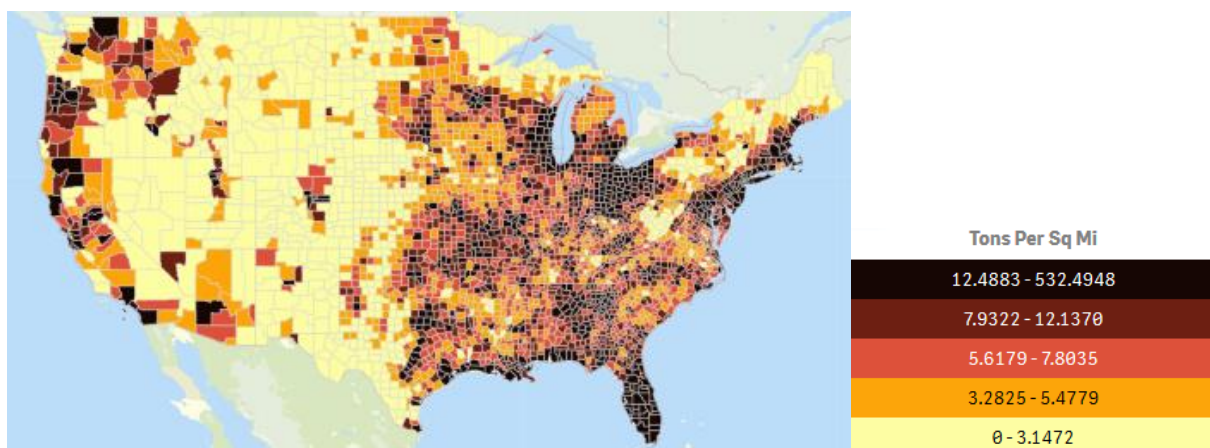

Although the NEI does not estimate emissions of PM<sub>10-2.5</sub> specifically, estimates of PM<sub>10</sub> emissions can provide insight into sources of coarse particles. Thus, the discussion below focuses on PM<sub>10</sub> emissions. The relative contributions of key sources to national PM<sub>10</sub> emissions, based on the 2014 NEI, are shown in Figure 2-4. Total PM<sub>10</sub> emissions are estimated to be about 13 million tons. National emissions of PM<sub>10</sub> are dominated by dust and agriculture, contributing a combined 75% of the total emissions. Current NEI estimates of dust emissions across the U.S. are based on limited emissions profile and activity information. For a number of reasons, quantification of dust emissions is highly uncertain. Much like wildfires, dust emissions are common but intermittent emissions sources. Additionally, the suspension and resuspension of dust is difficult to quantify. Moreover, some dust particles in the PM<sub>10-2.5</sub> size range are also transported internationally and considered as a part of the background component of PM as opposed to a primary emission of coarse PM (U.S. EPA, 2019a, section 2.3.3).

As with PM<sub>2.5</sub>, the relative contributions of particular sources to total PM<sub>10</sub> emissions varies from location to location (e.g., depending on local climate, geography, degree of urbanization, etc.). However, unlike with PM<sub>2.5</sub>, the sectors included in Figure 2-4 and found to be the largest contributors to coarse PM emissions are expected to be among the most important contributors at both the national and more regional levels, particularly given the sources of the particles in these source categories (e.g., mineral dust, primary biological aerosols (including pollen), sea spray). As noted previously, the NEI does not include sources such as pollen, sea spray, windblown dust, or geogenic sources, though those sources also likely contribute to PM<sub>10</sub>

emissions. Figure 2-4 shows the national contributions to PM<sub>10</sub> emissions from particular source sectors and Figure 2-5 shows the emissions density map for PM<sub>10</sub>.

**Figure 2-4. Percent contribution of PM<sub>10</sub> emissions by national source sectors.** (Source: 2014 NEI)

**Figure 2-5. PM<sub>10</sub> Emissions Density Map, tons per square mile**

### **2.1.1.3 Sources Contributing to Emissions of PM Components and Precursor Gases**

Understanding the components of PM is particularly important for providing insight into which sources contribute to PM mass, as well as for better understanding the health and welfare effects of particles. Major components of PM<sub>2.5</sub> mass include sulfate (SO<sub>4</sub><sup>2-</sup>), nitrate (NO<sub>3</sub><sup>-</sup>), elemental or black carbon (EC or BC), organic carbon (OC), and crustal materials. Some of these PM components are emitted directly to the air (e.g., EC, BC) while others are formed secondarily through reactions by gaseous precursors (e.g., sulfate, nitrate). The following sections specifically discuss the sources that contribute to the specific PM<sub>2.5</sub> components, including particulate carbon (section 2.1.1.3.1) and precursor gases (section 2.1.1.3.2).

#### **2.1.1.3.1 Sources Contributing to Emissions of Particulate Carbon**

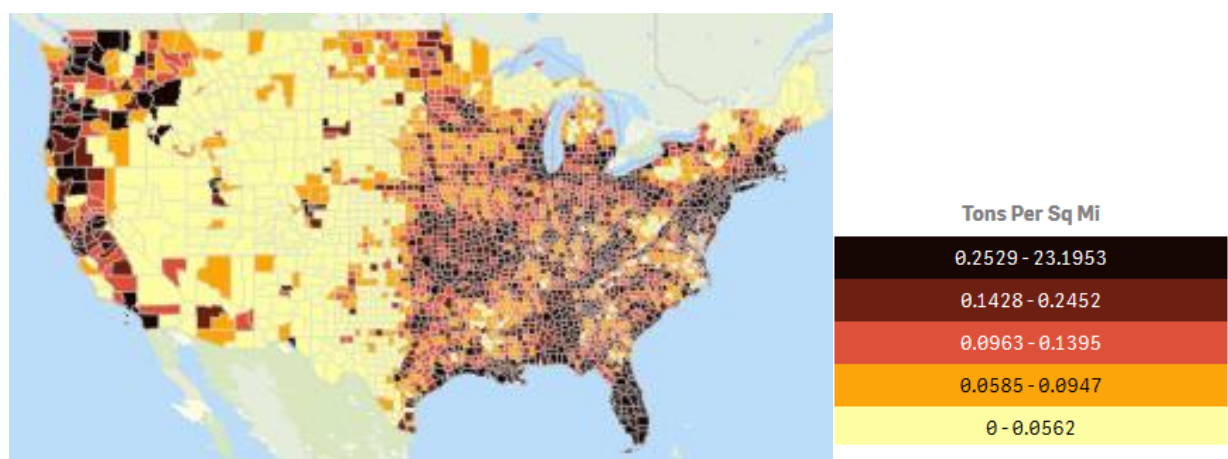

Of the directly emitted components of PM<sub>2.5</sub>, emissions of elemental (or black) carbon and organic carbon often make up the largest percentage of directly emitted PM<sub>2.5</sub> mass. Figure 2-6 illustrates the sources that contribute to national emissions of elemental and organic carbon based on the 2014 NEI. The top panel of Figure 2-6 shows that fires account for most (i.e., 53%) of the 1.5 million tons of particulate OC emissions estimated in the 2014 NEI, while the bottom panel of Figure 2-6 shows that fires and mobile sources (mostly diesel sources) contribute 80% of the estimated 431,000 tons of particulate EC in the 2014 NEI.

**Figure 2-6. Percent contribution to organic carbon (top panel) and elemental carbon (bottom panel) national emissions by source sectors. (Source: 2014 NEI)**

Figure 2-7 shows the emissions density map for elemental carbon. This map illustrates that the elemental carbon emissions signals are strong in the Southeast U.S. and parts of the West and Northwest U.S., where fires make substantial contributions to PM<sub>2.5</sub>. In addition, areas where diesel off-road and on-road sources are a large part of the emissions mix also stand out (urban and highway corridors). The OC density map (not shown) shows the highest emissions density in locations with substantial biomass burning activity, consistent with most of the OC emissions coming from fires (Figure 2-6).

**Figure 2-7. Elemental Carbon Emissions Density Map, tons per square mile**

#### **2.1.1.3.2 Sources Contributing to Emissions of Precursor Gases**

As discussed further in the ISA (U.S. EPA, 2019a, section 2.3.2.1), secondary PM is formed in the atmosphere by photochemical oxidation reactions of both inorganic and organic gas-phase precursors. Precursor gases include SO<sub>2</sub>, NO<sub>x</sub>, and volatile organic compound (VOC) gases of anthropogenic or natural origin (U.S. EPA, 2019a, section 2.3.2.1). Anthropogenic SO<sub>2</sub> and NO<sub>x</sub> are the predominant precursor gases in the formation of secondary PM<sub>2.5</sub>, and ammonia also plays an important role in the formation of nitrate PM by neutralizing sulfuric acid and nitric acid. In addition, atmospheric oxidation of VOCs, both anthropogenic and biogenic, is an important source of organic aerosols, particularly in summer. The semi-volatile and non-volatile products of VOC oxidation reactions can condense onto existing particles or can form new particles (U.S. EPA, 2009, section 3.3.2; U.S. EPA, 2019a, section 2.3.2).

Emissions of each of the precursor gases noted above are estimated in the NEI and have unique source signatures at the national level. Figure 2-8 illustrates the source contributions at the national level for these PM<sub>2.5</sub> precursor gases. As shown in Panel A in Figure 2-8, stationary fuel combustion sources contribute nearly 80% of the estimated total of 4.8 million tons of national SO<sub>2</sub> national emissions. Within this source category, nearly all of the SO<sub>2</sub> emitted to the

atmosphere comes from electricity generating units, or EGUs. NO<sub>x</sub> emissions, shown in panel B, are emitted by a range of combustion sources, including mobile sources (58%) and stationary fuel combustion sources (24%). In the 2014 NEI, there is an estimated total of 14.4 million tons of NO<sub>x</sub> emitted. Of the total estimate of 3.6 million tons of ammonia (NH<sub>3</sub>) emissions shown in panel C of Figure 2-8, NH<sub>3</sub> emissions are dominated by the agriculture source categories. In these categories, NH<sub>3</sub> is predominantly emitted by livestock waste from animal husbandry operations (55%) and fertilizer application (25%). In urban areas, on-road mobile sources may also contribute significantly to NH<sub>3</sub> emissions (U.S. EPA, 2019a, Figure 2-3; Sun et al., 2014). Of the estimated 17 million tons of VOC emissions from anthropogenic sources, fires (26%) and mobile sources (24%) are the largest contributors to national VOC emissions, along with industrial processes (23%), as shown in panel D.

**Figure 2-8. Percent contribution to sulfur dioxide (panel A), oxides of nitrogen (panel B), ammonia (panel C), and anthropogenic volatile organic compounds (panel D) national emissions by source sectors. (Source: 2014 NEI)**

Figure 2-9 to Figure 2-12 below show the emissions density maps corresponding to each of the PM<sub>2.5</sub> precursors included in Figure 2-8.

**Figure 2-12. Anthropogenic (including wildfires) VOC Emissions Density Map, tons per square mile**

### 2.1.1.3.3 Uncertainty in Emission Estimates

Accuracy in an emissions inventory reflects the extent to which the inventory represents the actual emissions that occurred. Anthropogenic emissions of air pollutants result from a variety of sources such as power plants, industrial sources, motor vehicles and agriculture. The emissions from any individual source typically vary in both time and space. It is not practically possible to monitor each of the emission sources individually and, therefore, emission inventories necessarily contain assumptions, interpolation and extrapolation from a limited set of sample data.

The NEI process is based on a “bottom up” approach to developing emission estimates. This means that a combination of activity and an appropriate emissions factor is used to estimate emissions for all processes. For the thousands of sources that make up the NEI, there is uncertainty in one or both of these factors. For some sources, such as EGUs, direct emission measurements enable the emission factors to be more certain than for sources without such direct measurements. For example, emission factors for residential wood combustion are taken from information available in the literature, regardless of its pedigree and direct applicability to the

source in question. Many of these issues related to the analysis of uncertainty in the NEI are discussed by Day et al., 2019).

It is not clear how uncertainties in emission estimates affect air quality modeling, as there are no numerical empirical uncertainty estimates available for the NEI. However, by comparing modeled concentrations to ambient measurements, overall uncertainty in model outputs can be characterized. Some of this uncertainty in model outputs is likely due to uncertainty in emission estimates.

## **2.2 AMBIENT PM MONITORING METHODS AND NETWORKS**

To promote uniform enforcement of the air quality standards set forth under the CAA and to achieve the degree of public health and welfare protection intended for the NAAQS, the EPA established PM Federal Reference Methods (FRMs)<sup>4</sup> for both PM<sub>10</sub> and PM<sub>2.5</sub> (40 CFR Appendix J and L to Part 50) and performance requirements for approval of Federal Equivalent Methods (FEMs) (40 CFR Part 53). Amended following the 2006 and 2012 PM NAAQS reviews, the current PM monitoring network relies on FRMs and automated continuous FEMs, in part to support changes necessary for implementation of the revised PM standards. The requirements for measuring ambient air quality and reporting ambient air quality data and related information are the basis for 40 CFR Appendices A through E to Part 58.

The EPA and its partners at state, local, and tribal monitoring agencies manage and operate the nation's ambient air monitoring networks. The EPA provides minimum monitoring requirements for criteria pollutants and related monitoring (e.g., the Chemical Speciation Network (CSN)), including identification of an FRM for criteria pollutants and guidance documents to support implementation and operation of the networks. Monitoring agencies carry out and perform ambient air monitoring in accordance with the EPA's requirements and guidance as well as often meeting their own state monitoring needs that may go beyond the minimum federal requirements. Data from the ambient air monitoring networks are available from two national databases: 1) the Air Quality System (AQS) database, which is the EPA's long-term repository of ambient air monitoring data and 2) the AirNow database, which provides near real-time data used in public reporting and forecasting of the Air Quality Index (AQI).<sup>5</sup>

---

<sup>4</sup> FRMs provide the methodological basis for comparison to the NAAQS and also serve as the "gold-standard" for the comparison of other methods being reviewed for potential approval as equivalent methods. The EPA keeps a complete list of designated reference and equivalent methods available on its Ambient Monitoring Technology Information Center (AMTIC) website (<https://www.epa.gov/amtic/air-monitoring-methods-criteria-pollutants>).

<sup>5</sup> The AQI translates air quality data into numbers and colors to help people understand when to take action to protect their health against ambient air concentrations of criteria pollutants.

The EPA and monitoring agencies manage and operate robust national networks for both PM<sub>10</sub> and PM<sub>2.5</sub>, as these are the two measurement programs directly supporting the PM NAAQS. PM<sub>10</sub> measurements are based on gravimetric mass, while PM<sub>2.5</sub> measurements include gravimetric mass and chemical speciation. A smaller network of stations is operating and reporting data for PM<sub>10-2.5</sub> gravimetric mass and a few monitors are operated to support special projects, including pilot studies, for continuous speciation and particle count data. Monitoring networks and additional monitoring efforts for each of the various PM size fractions and for PM composition are discussed below.<sup>6</sup> Section 2.2.1 provides information on monitoring for total suspended particulates (TSP), section 2.2.2 provides information on monitoring for PM<sub>10</sub>, section 2.2.3 provides information on monitoring PM<sub>2.5</sub>, section 2.2.4 provides information on monitoring for PM<sub>10-2.5</sub>, and section 2.2.5 provides information on additional PM metrics. All sampler and monitor counts provided in these sections are based on data submitted to the EPA for calendar year 2018, unless otherwise noted. Figure 2-13 below illustrates the changes in PM monitoring stations reporting to the EPA's AQS database by size fraction since 1970.

**Figure 2-13. PM Monitoring stations reporting to EPA's AQS database by PM size fraction, 1970-2018.**

### 2.2.1 Total Suspended Particulates (TSP) Sampling

The EPA first established NAAQS for PM in 1971, based on the original air quality criteria document (DHEW, 1969). The reference method specified for determining attainment of

<sup>6</sup> More information on ambient monitoring networks can be found at <https://www.epa.gov/amtic>

the original standards was the high-volume sampler, which collects PM up to a nominal size of 25 to 45  $\mu\text{m}$  (referred to as total suspended particles or TSP). TSP was replaced by  $\text{PM}_{10}$  as the indicator for the PM NAAQS in the 1987 final rule (52 FR 24854, July 1, 1987). TSP sampling remains in operation at a limited number of locations primarily to provide aerosol collection for TSP lead (Pb) analysis as well as for instances where a state may continue to have state standards for TSP. The size of the TSP network peaked in the mid-1970s when over 4,300 TSP samplers were in operation. As of 2018, there were 164 TSP samplers still in operation as part of the Pb monitoring program; of these, 41 also report TSP mass.

### 2.2.2 $\text{PM}_{10}$ Monitoring

To support the 1987  $\text{PM}_{10}$  NAAQS, the EPA and its state and local partners implemented the first size-selective PM monitoring network in 1990 with the establishment of a  $\text{PM}_{10}$  network consisting of mainly high-volume samplers. The network design criteria emphasize monitoring at middle<sup>7</sup> and neighborhood<sup>8</sup> scales to effectively characterize the emissions from both mobile and

---

<sup>7</sup> For  $\text{PM}_{10}$ , middle-scale is defined as follows: Much of the short-term public exposure to  $\text{PM}_{10}$  is on this scale and on the neighborhood scale. People moving through downtown areas or living near major roadways or stationary sources, may encounter particulate pollution that would be adequately characterized by measurements of this spatial scale. Middle scale  $\text{PM}_{10}$  measurements can be appropriate for the evaluation of possible short-term exposure public health effects. In many situations, monitoring sites that are representative of micro-scale or middle-scale impacts are not unique and are representative of many similar situations. This can occur along traffic corridors or other locations in a residential district. In this case, one location is representative of a neighborhood of small scale sites and is appropriate for evaluation of long-term or chronic effects. This scale also includes the characteristic concentrations for other areas with dimensions of a few hundred meters such as the parking lot and feeder streets associated with shopping centers, stadia, and office buildings. In the case of  $\text{PM}_{10}$ , unpaved or seldomly swept parking lots associated with these sources could be an important source in addition to the vehicular emissions themselves.

<sup>8</sup> For  $\text{PM}_{10}$ , neighborhood scale is defined as follows: Measurements in this category represent conditions throughout some reasonably homogeneous urban sub-region with dimensions of a few kilometers and of generally more regular shape than the middle scale. Homogeneity refers to the particulate matter concentrations, as well as the land use and land surface characteristics. In some cases, a location carefully chosen to provide neighborhood scale data would represent not only the immediate neighborhood but also neighborhoods of the same type in other parts of the city. Neighborhood scale  $\text{PM}_{10}$  sites provide information about trends and compliance with standards because they often represent conditions in areas where people commonly live and work for extended periods. Neighborhood scale data could provide valuable information for developing, testing, and revising models that describe the larger-scale concentration patterns, especially those models relying on spatially smoothed emission fields for inputs. The neighborhood scale measurements could also be used for neighborhood comparisons within or between cities.

stationary sources, although not ruling out microscale<sup>9</sup> monitoring in some instances (40 CFR Part 58 Appendix D, 4.6 (b)). The PM<sub>10</sub> monitoring network peaked in size in 1995 with 1,665 stations reporting data.

In 2018, there were 714 PM<sub>10</sub> stations in operation to support comparison of the PM<sub>10</sub> data to the NAAQS, trends, and reporting and forecasting of the AQI. Though the PM<sub>10</sub> network is relatively stable, monitoring agencies may continue divesting of some of the PM<sub>10</sub> monitoring stations where concentration levels are low relative to the NAAQS.

While the PM<sub>10</sub> network is national in scope, there are areas of the west, such as California and Arizona, with substantially higher PM<sub>10</sub> station density than the rest of the country. In the PM<sub>10</sub> mass network, 365 of the stations operate automated continuous mass monitors approved as FEMs and 391 operate FRMs. About 40 of the PM<sub>10</sub> stations have collocation with both continuous FEMs and FRMs. About two thirds of the PM<sub>10</sub> stations with FRMs operate on a sample frequency of one in every sixth day, with about 70 operating every third day and 60 operating every day.

### **2.2.3 PM<sub>2.5</sub> Monitoring**

To support the 1997 PM<sub>2.5</sub> NAAQS, the first PM standard with PM<sub>2.5</sub> as an indicator, the EPA and states implemented a PM<sub>2.5</sub> network consisting of ambient air monitoring sites with mass and/or chemical speciation measurements. Network operation began in 1999 with nearly 1,000 monitoring stations operating FRMs to measure fine particle mass. The PM<sub>2.5</sub> monitoring program remains one of the major ambient air monitoring programs operated across the country.

For most urban locations PM<sub>2.5</sub> monitors are sited at the neighborhood scale,<sup>10</sup> where PM<sub>2.5</sub> concentrations are reasonably homogeneous throughout an entire urban sub-region. In each

---

<sup>9</sup> For PM<sub>10</sub>, microscale is defined as follows: This scale would typify areas such as downtown street canyons, traffic corridors, and fence line stationary source monitoring locations where the general public could be exposed to maximum PM<sub>10</sub> concentrations. Microscale particulate matter sites should be located near inhabited buildings or locations where the general public can be expected to be exposed to the concentration measured. Emissions from stationary sources such as primary and secondary smelters, power plants, and other large industrial processes may, under certain plume conditions, likewise result in high ground level concentrations at the microscale. In the latter case, the microscale would represent an area impacted by the plume with dimensions extending up to approximately 100 meters. Data collected at microscale sites provide information for evaluating and developing hot spot control measures.

<sup>10</sup> For PM<sub>2.5</sub>, neighborhood scale is defined as follows: Measurements in this category would represent conditions throughout some reasonably homogeneous urban sub-region with dimensions of a few kilometers and of generally more regular shape than the middle scale. Homogeneity refers to the particulate matter concentrations, as well as the land use and land surface characteristics. Much of the PM<sub>2.5</sub> exposures are expected to be associated with this scale of measurement. In some cases, a location carefully chosen to provide neighborhood scale data would represent the immediate neighborhood as well as neighborhoods of the same type in other parts of the city. PM<sub>2.5</sub> sites of this kind provide good information about trends and compliance with standards because they often represent conditions in areas where people commonly live and work for periods comparable to those specified in the NAAQS. In general, most PM<sub>2.5</sub> monitoring in urban areas should have this scale.

CBSA with a monitoring requirement, at least one PM<sub>2.5</sub> monitoring station representing area-wide air quality is to be sited in an area of expected maximum concentration. Sites that represent relatively unique microscale, localized hot-spot, or unique middle scale impact sites are only eligible for comparison to the 24-hour PM<sub>2.5</sub> NAAQS.

There are three main components of the current PM<sub>2.5</sub> monitoring program: FRMs, PM<sub>2.5</sub> continuous mass monitors, and CSN samplers. The FRMs are primarily used for comparison to the NAAQS, but also serve other important purposes such as developing trends and evaluating the performance of PM<sub>2.5</sub> continuous mass monitors. PM<sub>2.5</sub> continuous mass monitors are automated methods primarily used to support forecasting and reporting of the AQI, but are also used for comparison to the NAAQS where approved as FEMs. The CSN and related Interagency Monitoring of Protected Visual Environments (IMPROVE) network are used to provide chemical composition of the aerosol which serve a variety of objectives. This section provides an overview of each of these components of the PM<sub>2.5</sub> monitoring program and of recent changes to PM<sub>2.5</sub> monitoring requirements.

#### **2.2.3.1 Federal Reference Method and Continuous Monitors**

As noted above, the PM<sub>2.5</sub> monitoring network began operation in 1999 with nearly 1,000 monitoring stations operating FRMs. The PM<sub>2.5</sub> FRM network peaked in operation in 2001 with over 1,150 monitoring stations. In the PM<sub>2.5</sub> network, in 2018 there were 624 FRM filter-based samplers that provide 24-hour PM<sub>2.5</sub> mass concentration data. Of these operating FRMs, 70 are providing daily PM<sub>2.5</sub> data, 422 every third day, and 132 every sixth day.

As of 2018, there are 940 continuous PM<sub>2.5</sub> mass monitors that provide hourly data on a near real-time basis reporting across the country. A total of 579 of the PM<sub>2.5</sub> continuous monitors are FEMs and therefore used both for comparison with the NAAQS and to report the AQI. Another 361 monitors not approved as FEMs are operated primarily to report the AQI. These legacy PM<sub>2.5</sub> continuous monitors were largely purchased prior to the availability of PM<sub>2.5</sub> continuous FEMs.

The first method approved as a continuous PM<sub>2.5</sub> FEM was the Met One BAM 1020. This method, approved in 2008, accounts for just over 50% of the operating PM<sub>2.5</sub> continuous FEMs in the country. The EPA has approved a total of 11 PM<sub>2.5</sub> continuous methods as FEMs. Other methods approved as continuous PM<sub>2.5</sub> FEMs include beta attenuation from multiple instrument manufacturers; optical methods such as the GRIMM and Teledyne T640; and methods employing the Tapered Element Oscillating Microbalance (TEOM) with a Filter Dynamic Measurement System (FDMS) manufactured by Thermo Fisher Scientific.

The quality of the data generated by PM<sub>2.5</sub> FRMs and automated FEMs were analyzed for years 2016-2018. Data quality terms for measurement uncertainty regularly assessed in the

PM<sub>2.5</sub> monitoring program include precision and bias. Precision is calculated by comparing data from collocated methods of the same make and model operated by the same monitoring organization. Bias is calculated by comparing data from routinely operated FRMs or automated FEMs by the monitoring organization and comparing that to data from reference method audit samplers temporarily collocated and operated independently from the staff in the monitoring organization. Goals for measurement uncertainty are defined in Appendix A to 40 CFR Part 58. They state “Measurement Uncertainty for Automated and Manual PM<sub>2.5</sub> Methods. The goal for acceptable measurement uncertainty is defined for precision as an upper 90 percent confidence limit for the coefficient of variation (CV) of 10 percent and  $\pm 10$  percent for total bias.” The most recent three-year average estimate of national aggregate PM<sub>2.5</sub> FRM precision is 8.2% and bias is -4.7%.

Automated PM<sub>2.5</sub> FEMs include a wide variety of approved methods which can have different measurement principles. Data aggregated across all automated FEMs result in a collocated precision of 18.6% and a bias as compared to the reference method audit program of +7.6%. When evaluating automated FEMs as individual methods, only two of the seven methods with available collocated precision data meet the measurement uncertainty goal; however, as explained in the Notice of Proposed Rulemaking, January 17, 2006<sup>11</sup> when considering a requirement for approval of candidate FEMs: “Statistical analyses based on the DQO model show that the precision of a candidate method is not, statistically, very important to annual concentration averages used for NAAQS attainment decisions, but would be important for a daily standard.” When evaluating automated FEMs as individual methods for bias, eight of ten methods with data available to calculate a performance evaluation bias meet this goal. In summary, PM<sub>2.5</sub> automated FEMs tend to have higher collocated precision than FRMs and tend to have a positive bias relative to both State and local operated FRMs as well as performance evaluation audit FRMs.

### **2.2.3.2 Chemical Speciation and IMPROVE Networks**

Due to the complex nature of fine particles, the EPA and states implemented the CSN to better understand the components of fine particle mass at selected locations across the country. The CSN was first piloted at 13 sites in 2000, and after the pilot phase, the program continued with deployment of the Speciation Trends Network (STN) later that year. The CSN ultimately grew to 54 trends sites and peaked in operation in 2005 with 252 stations: the 54 trends stations and nearly 200 supplemental stations. The original CSN program had multiple sampler configurations including the Thermo Andersen RAAS, Met One SASS/SuperSASS, and URG

---

<sup>11</sup> <https://www.govinfo.gov/content/pkg/FR-2006-01-17/pdf/06-177.pdf>

MASS. During the 2000s, the EPA and states worked to align the network to one common sampler for elements and ions, which was the Met One SASS/SuperSASS. In 2005, the CASAC provided recommendations to the EPA for making changes to the CSN. These changes were intended to improve data comparability with the rural IMPROVE carbon concentration data. To accomplish this, the EPA replaced the existing carbon channel sampling and analysis methods with a new modified IMPROVE version III module C sampler, the URG 3000N. Implementation of the new carbon sampler and analysis was broken into three phases starting in May 2007 through October 2009.

In the 2018 PM<sub>2.5</sub> CSN, long-term measurements are made at about 76 largely urban locations comprised of either the STN or the National Core (NCore) network.<sup>12</sup> NCore is a multipollutant network measuring particles, gases, and basic meteorology that has been in formal operation since January 1, 2011. Particle measurements made at NCore include PM<sub>2.5</sub> filter-based mass, which is largely the FRM, except in some rural locations that utilize the IMPROVE program PM<sub>2.5</sub> mass filter-based measurement; PM<sub>2.5</sub> speciation using either the CSN program or IMPROVE program; and PM<sub>10-2.5</sub> mass utilizing an FRM, FEM or IMPROVE for some of the rural locations. As of 2018, the NCore network includes a total of 78 stations of which 63 are in urban or suburban stations designed to provide representative population exposure and another 15 rural stations designed to provide background and transport information. The NCore network is deployed in all 50 States, DC, and Puerto Rico with at least one station in each state and two or more stations in larger population states (California, Florida, Illinois, Michigan, New York, North Carolina, Ohio, Pennsylvania, and Texas).

Both the STN and NCore networks are intended to remain in operation indefinitely. The CSN measurements at NCore and STN stations operate every third day. Another approximately 72 CSN stations, known as supplemental sites, are intended to be potentially less permanent locations used to support State Implementation Plan (SIP) development and other monitoring objectives.<sup>13</sup> Supplemental CSN stations typically operate every sixth day. In January 2015, 38 supplemental CSN stations that are largely located in the eastern half of the country stopped operations to ensure a sustainable CSN network moving forward.<sup>14</sup>

---

<sup>12</sup> In most cases where a city has an STN station, it is located at the same site as the NCore station. In a few cases, a city may have an STN station located at a different location than the NCore station.

<sup>13</sup> See <https://www3.epa.gov/ttn/amtic/speciepg.html> for more information on the PM<sub>2.5</sub> speciation monitoring program.

<sup>14</sup> Based on assessments of the CSN network and IMPROVE protocol sites, monitoring resources were redistributed to focus on new or high priorities. More information on the CSN and IMPROVE protocol assessments is available at <https://www.sdas.battelle.org/CSNAssessment/html/Default.html>.

Specific components of fine particles are also measured through the IMPROVE monitoring program<sup>15</sup> which supports regional haze characterization and tracks changes in visibility in Class I areas as well as many other rural and some urban areas. As of 2018, the IMPROVE network includes 110 monitoring locations that are part of the base network supporting regional haze and another 46 locations operated as IMPROVE protocol sites where a monitoring agency has requested participation in the program. These IMPROVE protocol sites operate the same way as the IMPROVE program, but they may serve several monitoring objectives (i.e., the same objectives as the CSN) and are not explicitly tied to the Regional Haze Program. Samplers at IMPROVE stations operate every third day. In January 2016, eight IMPROVE protocol stations stopped operating to ensure a sustainable IMPROVE program moving forward. Details on the process and outcomes of the CSN supplemental and IMPROVE protocol assessments used to identify sites that would no longer be funded are available on an interactive website.<sup>16</sup> Together, the CSN and IMPROVE data provide chemical species information for fine particles that are critical for use in health and epidemiologic studies to help inform reviews of the primary PM NAAQS and can be used to better understand visibility through calculation of light extinction using the IMPROVE algorithm<sup>17</sup> to support reviews of the secondary PM NAAQS.

The quality of the data generated by the PM<sub>2.5</sub> speciation networks (CSN and IMPROVE) is assessed regularly, using a variety of metrics. Overall network precision, including uncertainties associated with both field operations and laboratory analyses, is assessed using the subset of sites with collocated samplers. Fractional uncertainty is one metric that both speciation networks regularly calculates using collocated data pairs above the MDL and reflects the overall percent uncertainty for the measurements. For CSN data collected between November 2015 and December 2016, the fractional uncertainties range from 6.6% for sulfate to 31.4% for chlorine.<sup>18</sup>

---

<sup>15</sup> Recognizing the importance of visual air quality, Congress included legislation in the 1977 Clean Air Act to prevent future and remedy existing visibility impairment in Class I areas. To aid the implementation of this legislation, the IMPROVE program was initiated in 1985 and substantially expanded in 2000-2003. This program implemented an extensive long-term monitoring program to establish the current visibility conditions, track changes in visibility and determine causal mechanism for the visibility impairment in the National Parks and Wilderness Areas. For more information, see <https://www3.epa.gov/ttn/amtic/visdata.html>.

<sup>16</sup> See the Chemical Speciation Network Assessment Interactive Website at: <https://www.sdas.battelle.org/CSNAssessment/html/Default.html>.

<sup>17</sup> The IMPROVE algorithm is an equation to estimate light extinction based on the measured concentration of several PM components and is used to track visibility progress in the Regional Haze Rule. More information about the IMPROVE algorithm is at available at: <http://vista.cira.colostate.edu/Improve/the-improve-algorithm>.

<sup>18</sup> [https://airquality.ucdavis.edu/sites/g/files/dgvnsk1671/files/inline-files/CSN\\_AnnualReport\\_2016Data\\_03.06.2019\\_FINAL\\_APPROVED.pdf](https://airquality.ucdavis.edu/sites/g/files/dgvnsk1671/files/inline-files/CSN_AnnualReport_2016Data_03.06.2019_FINAL_APPROVED.pdf)

For IMPROVE data collected in 2016 and 2017, the fractional uncertainties range from 2% for sulfur and sulfate to 27% for phosphorous.<sup>19</sup> In general, uncertainties are higher for species with concentrations near the detection limit. Bias for the speciation networks can be assessed using reports from interlaboratory comparisons.<sup>20</sup>

### **2.2.3.3 Recent Changes to PM<sub>2.5</sub> Monitoring Requirements**

Key changes made to the EPA's monitoring requirements as a result of the 2012 PM NAAQS review included the addition of PM<sub>2.5</sub> monitoring at near-road locations in core-based statistical areas (CBSAs) over 1 million in population; the clarification of terms used in siting of PM<sub>2.5</sub> monitors and their applicability to the NAAQS; and the provision of flexibility on data uses to monitoring agencies where their PM<sub>2.5</sub> continuous monitors are not providing data that meets the performance criteria used to approve the continuous method as an FEM. The addition of PM<sub>2.5</sub> monitoring at near-road locations was phased in from 2015 to 2017. On January 1, 2015, 22 CBSAs with a population of 2.5 million or more were required to have a PM<sub>2.5</sub> FRM or FEM operating at a near-road monitoring station. On January 1, 2017, 30 CBSAs with a population between 1 million and 2.5 million were required to have a PM<sub>2.5</sub> FRM or FEM operating at a near-road monitoring station.

The terms clarified as a part of the 2012 rulemaking ensure consistency with all other NAAQS and long-standing definitions used by the EPA (78 FR 3234, January 15, 2013). The flexibility provided to monitoring agencies ensures that the incentives of utilizing PM<sub>2.5</sub> continuous monitors (e.g., efficiencies in operation and availability of hourly data in near-real time) are realized without having potentially poor performing data be used in situations where the data is not applicable to the NAAQS (78 FR 3241, January 15, 2013).

### **2.2.4 PM<sub>10-2.5</sub> Monitoring**

In the 2006 PM NAAQS review, the EPA promulgated a new FRM for the measurement of PM<sub>10-2.5</sub> mass in ambient air. Although the standard for coarse particles uses a PM<sub>10</sub> indicator, a new FRM for PM<sub>10-2.5</sub> mass was developed to provide a basis for approving FEMs and to promote the gathering of scientific data to support future reviews of the PM NAAQS. The PM<sub>10-2.5</sub> FRM (or approved FEMs, where available) was implemented at required NCore stations by January 1, 2011. In addition to NCore, there are other collocated PM<sub>10</sub> and PM<sub>2.5</sub> low-volume FRMs operating across the country that are essentially providing the PM<sub>10-2.5</sub> FRM measurement by the difference method.

---

19 [http://vista.cira.colostate.edu/improve/wp-content/uploads/2019/11/IMPROVE\\_QAReport\\_11.15.2019.pdf](http://vista.cira.colostate.edu/improve/wp-content/uploads/2019/11/IMPROVE_QAReport_11.15.2019.pdf)

20 <https://www3.epa.gov/ttn/amtic/pmspec.html>

PM<sub>10-2.5</sub> measurements are currently performed across the country at NCore stations, IMPROVE monitoring stations, and at a few additional locations where state or local agencies choose to operate a PM<sub>10-2.5</sub> method. For urban NCore stations and other State and Local Air Monitoring Stations (SLAMS) the method employed is either a PM<sub>10-2.5</sub> FRM, which is performed using a low-volume PM<sub>10</sub> FRM collocated with a low volume PM<sub>2.5</sub> FRM of the same make and model, or FEMs for PM<sub>10-2.5</sub>, including filter-based dichotomous methods and continuous methods of which several makes and models are approved. Filter-based PM<sub>10-2.5</sub> measurements at NCore (i.e., the FRM or dichotomous filter-based FEM) operate every third day, while continuous methods have data available every hour of every day. PM<sub>10-2.5</sub> filter-based methods at other SLAMS typically operate every third or sixth day. For IMPROVE, which is largely a rural network, PM<sub>10-2.5</sub> measurements are made with two sample channels; one each for PM<sub>10</sub> and PM<sub>2.5</sub>. All IMPROVE program samplers operate every third day. All together there were 279 stations in 2018 where PM<sub>10-2.5</sub> data were being reported to the AQS database.

There is no operating chemical speciation network for characterizing the specific components of coarse particles. In 2015, Washington University at St. Louis, under contract to the U.S. EPA, reported on a coarse particle speciation pilot study with several objectives aimed at addressing this issue, such as evaluating a coarse particle species analyte list and evaluating sampling and analytical methods (U.S. EPA, 2015). The coarse particle speciation pilot study provides useful information for any organization wishing to pursue coarse particle speciation.

### **2.2.5 Additional PM Measurements and Metrics**

There are additional PM measurements and metrics made at a much smaller number of stations. These measurements may be associated with special projects or are complementary measurements to other networks where the monitoring agency has prioritized having the measurements. None of these measurements are required by regulation. They include PM measurements such as particle counts, continuous carbon, and continuous sulfate.

The EPA and state and local agencies have also been working together to pilot additional PM methods at near-road monitoring stations that may be of interest to data users. These methods include such techniques as particle counters, particle size distribution, and black carbon by aethalometer. These methods and their rationale for use at near-road monitoring stations are described in a Technical Assistance Document (TAD) on NO<sub>2</sub> near-road monitoring (U.S. EPA, 2012, section 16).

Aethalometer measurements of the concentration of optically absorbing particles have been submitted to AQS for many years. Data uses include characterizing black carbon and wood smoke. Ambient air monitoring stations that may have aethalometers include some of the near-road monitoring stations and National Air Toxics Trends Stations (NATTS). Data from about 72

monitoring sites across the county are being reported from aethalometers. While aethalometer data is available at high time resolutions (e.g., 5-minute data), it is typically reported to the AQS database in 1-hour periods.

Continuous elemental and organic carbon data were monitored at select locations participating in a pilot of the Sunset EC/OC analyzer as well as a few additional sites that were already operating before the EPA initiated the pilot study.<sup>21</sup> The Sunset EC/OC analyzer provides high time resolution carbon data, typically every hour, but in some remote locations the instrument is programmed to run every two hours to ensure collection of enough aerosol. The data from the Sunset EC/OC analyzer was compared to filter-based carbon methods from the carbon channel of the CSN program. The Sunset EC/OC analyzer was operated at each of the study sites for at least three years. Results from this pilot study are available in an EPA report (U.S. EPA, 2019b). A key finding from the study suggests that when the Sunset instrument was working well, OC and optical EC were comparable to CSN OC and EC; however, the time and resources needed to keep a Sunset analyzer operational did not merit replacement of CSN OC and EC measurements.

As of 2018, continuous sulfate is measured at four remaining monitoring sites, one in Maine and three in New York State. Several other stations have historical data but are no longer monitoring continuous sulfate. Discontinuing monitoring efforts for continuous sulfate is likely an outcome of the significantly lower sulfate concentrations throughout the east where these methods were operated. The continuous sulfate analyzer provides hourly data and these data can be readily compared to 24-hour sulfate data which are collected from the ion channel in both the CSN and IMPROVE programs.

In addition, over the last few years, the EPA has investigated the use of several PM sensor technologies as one of several areas of research intended to address the next generation of air measurements. The investigation into air sensors is envisioned to work towards near real-time or continuous measurement options that are smaller, cheaper, and more portable than traditional FRM or FEM methods. These sensor devices have the potential to be used in several applications such as identifying hotspots, informing network design, providing personal exposure monitoring, supporting risk assessments, and providing background concentration data for permitting. The EPA has hosted workshops and published several documents and peer-reviewed articles on this work.<sup>22</sup>

---

<sup>21</sup> The six sites that participated in the study were Washington, DC; Chicago, IL; St. Louis, MO; Houston, TX; Las Vegas, NV; and Los Angeles, CA.

<sup>22</sup> For more information, see <https://www.epa.gov/sciencematters/epas-next-generation-air-measuring-research> and <https://www.epa.gov/air-sensor-toolbox/air-sensor-toolbox-what-epa-doing#pane-1>.

## 2.3 AMBIENT AIR CONCENTRATIONS

This section summarizes available information on recent ambient PM concentrations. Section 2.3.1 presents trends in emissions of PM and precursor gases, while section 2.3.2 presents trends in monitored ambient concentrations of PM in the U.S. Section 2.3.3 discusses approaches for predicting ambient PM<sub>2.5</sub> by hybrid modeling approaches.

### 2.3.1 Trends in Emissions of PM and Precursor Gases

Direct emissions of PM have remained relatively unchanged in recent years, while emissions of some precursor gases have declined substantially.<sup>23</sup> As illustrated in Figure 2-14,<sup>24</sup> from 1990 to 2014, SO<sub>2</sub> emissions have undergone the largest declines while NH<sub>3</sub> emissions have undergone the smallest change. Declining SO<sub>2</sub> emissions during this time period are primarily a result of reductions at stationary sources such as EGUs, with substantial reductions also from mobile sources (U.S. EPA, 2019a, section 2.3.2.1). In more recent years (i.e., 2002 to 2014), emissions of SO<sub>2</sub> and NO<sub>x</sub> have undergone the largest declines, while direct PM<sub>2.5</sub> and NH<sub>3</sub> emissions have undergone the smallest changes, as shown in Table 2-1. Regional trends in emissions can differ from the national trends illustrated in Figure 2-14 and Table 2-1.<sup>25</sup> For example, Hand et al. (2012) studied reductions in EGU-related annual SO<sub>2</sub> emissions during the 2001–2010 period and found that while SO<sub>2</sub> emissions decreased throughout the U.S. by an average of 6.2% per year, the amount of change varied across the U.S. with the largest percent reductions in the western U.S. at 20.1% per year.

---

<sup>23</sup> More information on these trends, including details on methods and explanations on the noted changes over time is available at <https://gispub.epa.gov/neireport/2014/>.

<sup>24</sup> Emission trends in Figure 2-14 do not include wildfire emissions.

<sup>25</sup> State-specific emission trends data for 1990 to 2014 can be found at: <https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data>.

**Figure 2-14. National emission trends of PM<sub>2.5</sub>, PM<sub>10</sub>, and precursor gases from 1990 to 2014.**

**Table 2-1. Percent Changes in PM and PM precursor emissions in the NEI for the time periods 1990-2014 and 2002-2014.**

Pollutant	Percent Change in Emissions: 1990 to 2014	Percent Change in Emissions: 2002 to 2014	Major Sources
NH <sub>3</sub>	-21%	-10%	Agricultural Sources (Fertilizer and Livestock Waste), Fires
NO <sub>x</sub>	-50%	-48%	EGUs, Mobile Sources
SO <sub>2</sub>	-80%	-69%	EGUs, other Stationary Sources
VOCs	-38%	-15%	Solvents, Fires, Mobile Sources
PM <sub>2.5</sub>	-40%	-4%	Dust, Fires
PM <sub>10</sub>	-38%	-15%	Dust, Fires

## 2.3.2 Trends in Monitored Ambient Concentrations

### 2.3.2.1 National Characterization of PM<sub>2.5</sub> Mass

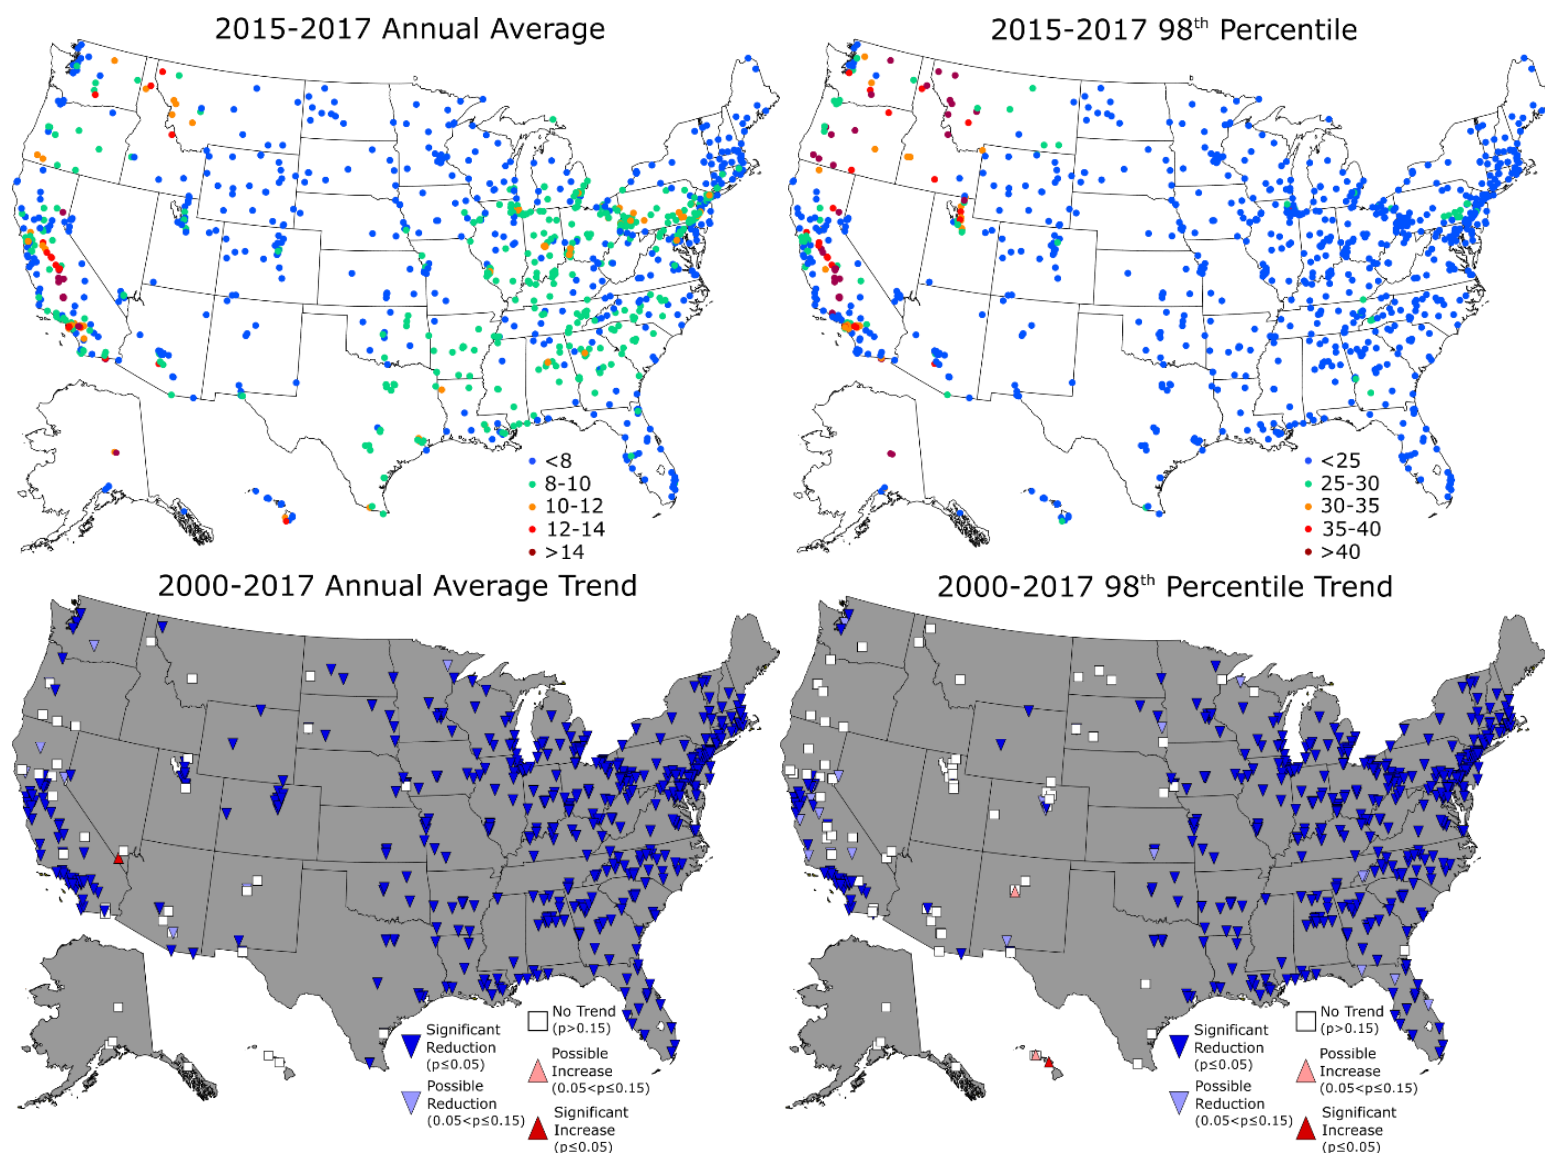

At long-term monitoring sites in the U.S., annual PM<sub>2.5</sub> concentrations from 2015 to 2017 averaged 8.0 µg/m<sup>3</sup> (ranging from 3.0 to 18.2 µg/m<sup>3</sup>) and the 98<sup>th</sup> percentiles of 24-hour concentrations averaged 20.9 µg/m<sup>3</sup> (ranging from 9.2 to 111 µg/m<sup>3</sup>). Figure 2-15 (top panels) shows that the highest ambient PM<sub>2.5</sub> concentrations occur in the west, particularly in California and the Pacific northwest. Much of the eastern U.S. has lower ambient concentrations, with annual average concentrations generally at or below 12.0 µg/m<sup>3</sup> and 98<sup>th</sup> percentiles of 24-hour concentrations generally at or below 30 µg/m<sup>3</sup>.

These concentrations are distinct from design values in part because they include days with episodic events like wildfires and dust storms which can have very high PM<sub>2.5</sub> and/or PM<sub>10</sub> concentrations. The EPA's Exceptional Events Rule,<sup>26</sup> most recently updated in 2016, describes the process by which these events can be excluded from the design values used for comparison to the NAAQS. For the remainder of Chapter 2, episodic events are included in the calculations of PM concentrations. When design values are discussed in Chapter 2, regionally-concurred exceptional events (as of July 2019) have been excluded from the analysis.<sup>27</sup>

---

<sup>26</sup> The final version of the 2016 Exceptional Events Rule can be accessed at [https://www.epa.gov/sites/production/files/2018-10/documents/exceptional\\_events\\_rule\\_revisions\\_2060-as02\\_final.pdf](https://www.epa.gov/sites/production/files/2018-10/documents/exceptional_events_rule_revisions_2060-as02_final.pdf).

<sup>27</sup> Regionally-concurred exceptional events are unusual or naturally-occurring events such as wildfires or high wind dust events that have 1) resulted in PM<sub>2.5</sub> concentrations above the level of the NAAQS, 2) been submitted by tribal, state or local air agencies under the EPA's Exceptional Events Rule to their respective EPA Region, and 3) received concurrence.

**Figure 2-15. Annual average and 98<sup>th</sup> percentile PM<sub>2.5</sub> concentrations (in  $\mu\text{g}/\text{m}^3$ ) from 2015-2017 (top) and linear trends and their associated significance (based on p-values) in PM<sub>2.5</sub> concentrations from 2000-2017 (bottom).**

Analysis of monthly data indicate distinct peaks in national ambient PM<sub>2.5</sub> concentrations during the summer and the winter (U.S. EPA, 2019a, Figure 2-22). Through 2008, the summer peaks reflected the highest national average PM<sub>2.5</sub> concentrations. These summer peaks in ambient PM<sub>2.5</sub> concentrations were largely a consequence of summertime peaks in SO<sub>2</sub> emissions from power plants in the eastern U.S., and subsequent sulfate formation. However, substantial reductions in SO<sub>2</sub> emissions (see above and U.S. EPA, 2019a, sections 2.5.1.1.1 and 2.5.2.2.1) have changed this pattern. Starting in 2009, winter peaks in national average PM<sub>2.5</sub> concentrations have been higher than those in the summer (U.S. EPA, 2019a, section 2.5.2.2.1). This pattern is illustrated by data from 2013 to 2015, when average winter PM<sub>2.5</sub> concentrations were about 11 µg/m<sup>3</sup>, average summer concentrations were about 9 µg/m<sup>3</sup>, and average spring and fall concentrations were about 7 µg/m<sup>3</sup> (Chan et al., 2018).

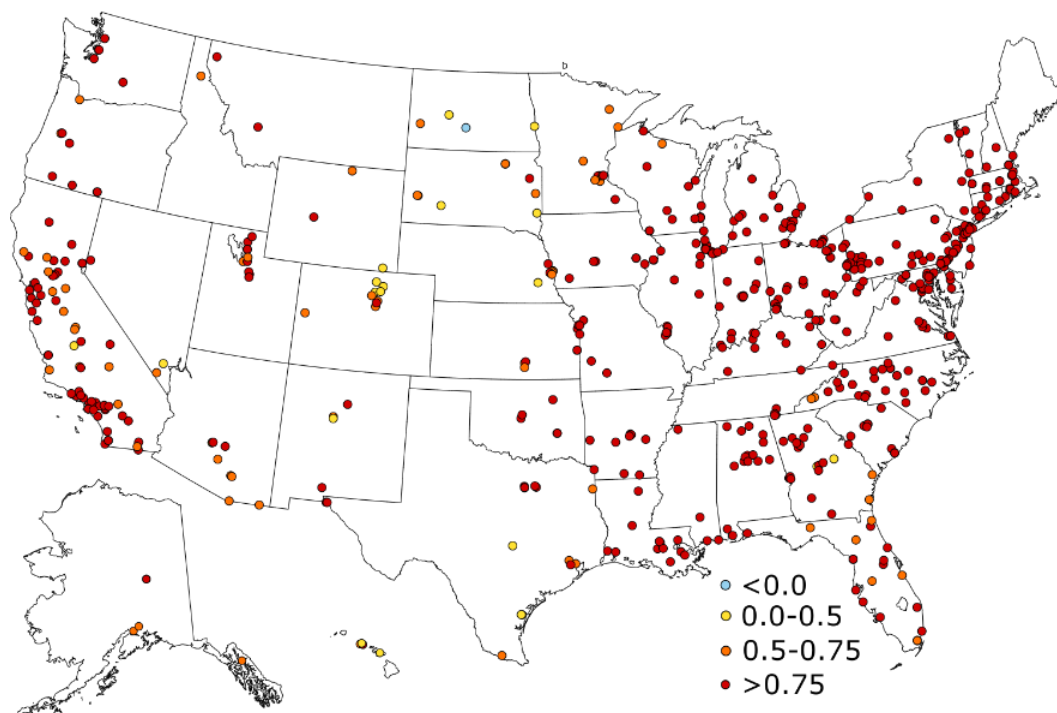

The ambient PM<sub>2.5</sub> concentrations in Figure 2-15 reflect the substantial reductions that have occurred across much of the U.S. over recent years (Figure 2-15, bottom panels and Figure 2-16). From 2000 to 2017, national annual average PM<sub>2.5</sub> concentrations have declined from 13.5 µg/m<sup>3</sup> to 8.0 µg/m<sup>3</sup>, a 41% decrease (Figure 2-16).<sup>28</sup> These declines have occurred at both urban and rural monitoring sites, although urban PM<sub>2.5</sub> concentrations remain consistently higher than those in rural areas (Chan et al., 2018) due to the so-called “urban increment” of PM<sub>2.5</sub> from local sources in an urban area that is additive to the regional and natural background PM<sub>2.5</sub> concentrations.

**Figure 2-16. Seasonally-weighted annual average PM<sub>2.5</sub> concentrations in the U.S. from 2000 to 2017 (429 sites).** (Note: The white line indicates the mean concentration while the gray shading denotes the 10<sup>th</sup> and 90<sup>th</sup> percentile concentrations.)

<sup>28</sup> See <https://www.epa.gov/air-trends/particulate-matter-pm25-trends> and <https://www.epa.gov/air-trends/particulate-matter-pm25-trends#pmnat> for more information.

Analyses at individual monitoring sites indicate that declines in ambient PM<sub>2.5</sub> concentrations have been most consistent across the eastern U.S. and in parts of coastal California, where both annual average and 98<sup>th</sup> percentiles of 24-hour concentrations have declined significantly (Figure 2-15, bottom panels). In contrast, trends in ambient PM<sub>2.5</sub> concentrations have been less consistent over much of the western U.S., with no significant changes since 2000 observed at some sites in the Pacific northwest, the northern Rockies and plains, and the southwest, particularly for 98<sup>th</sup> percentiles of 24-hour concentrations (Figure 2-15, bottom panels). Trends in annual average PM<sub>2.5</sub> concentrations have been highly correlated with trends in 98<sup>th</sup> percentiles of 24-hour concentrations at individual sites (Figure 2-17). Such correlations are highest across the eastern U.S. and in coastal California, and are somewhat lower, though still generally positive, at sites in the Central and Western U.S. (i.e., outside of coastal California).

**Figure 2-17. Pearson's correlation coefficient between annual average and 98<sup>th</sup> percentile of 24-hour PM<sub>2.5</sub> concentrations from 2000-2017.**

### **2.3.2.2 Characterization of PM<sub>2.5</sub> Mass at Finer Spatial and Temporal Scales**

#### **2.3.2.2.1 CBSA Maximum Annual Versus Daily Design Values**

Analysis of recent air quality indicates that maximum annual and daily PM<sub>2.5</sub> design values within a CBSA are positively correlated with some noticeable regional variability (Figure 2-18). In the Southeast, Northeast, and Industrial Midwest regions, the annual design values are high relative to the daily design values due in part to the infrequent impacts of episodic events

like wildfire or dust storms. On the other hand, the Northwest region has very high daily design values relative to the annual design values. This is due to episodically high PM<sub>2.5</sub> concentrations that affect the region, both from wintertime stagnation events and summer/fall wildfire smoke events.<sup>29</sup> The relatively small population and low emissions in the region result in much lower PM<sub>2.5</sub> concentrations during the other parts of the year not affected by these episodes.

**Figure 2-18. Scatterplot of CBSA maximum annual versus daily design values (2015-2017) with the solid black line representing the ratio of daily and annual NAAQS values.**

#### 2.3.2.2.2 PM<sub>2.5</sub> Near Major Roadways

Because of its longer atmospheric lifetime (U.S. EPA, 2019a, section 2.2), PM<sub>2.5</sub> is expected to exhibit less spatial variability on an urban scale than UFP or PM<sub>10-2.5</sub> (U.S. EPA, 2019a, section 2.5.1.2.1). Analyses in the 2009 ISA for PM indicated that correlations between PM<sub>2.5</sub> monitoring sites up to a distance of 100 km from each other were greater than 0.75 in most

<sup>29</sup> Due to the recent time period shown in Figure 2-18, it is likely that some of the annual and daily design values are affected by potential exceptional events associated with wildfire smoke that have yet to be regionally-concurred and removed from the design value calculations. The EPA defines exceptional events as unusual or natural-occurring events that affect air quality but are not reasonably controllable using techniques that tribal, state, or local air agencies may implement. This is especially likely for the daily design values in the Northwest region which experienced frequent wildfire smoke events during the 2015-2017 period.

urban areas. However, more substantial spatial variation has been reported for some urban areas, due in part to proximity between monitors and emissions sources (U.S. EPA, 2019a, section 2.5.1.2.1). The recent deployment of PM<sub>2.5</sub> monitors near major roads in large urban areas provides some insight into this spatial variation.

As discussed above, in the last review of the PM NAAQS the EPA required monitoring of PM<sub>2.5</sub>, along with NO<sub>2</sub> and CO, near major roads in CBSAs with populations greater than 1 million. PM<sub>2.5</sub> monitoring was required to start for the largest CBSAs at the beginning of 2015, and several years of data are now available for analysis at these sites. DeWinter et al. (2018) analyzed these data and found that the average near-road increment (difference between near-road PM<sub>2.5</sub> concentrations and the concentrations at other sites in the same CBSA) was 1.2 µg/m<sup>3</sup> for 2014 to 2015. The near-road increment has a diurnal cycle, with a peak during the morning rush hour (Figure 2-19). This near-road increment likely is additive to the urban increment of PM<sub>2.5</sub> from local sources in the CBSA including mobile sources on the numerous non-highway roads that are not monitored by the near-road network.

**Figure 2-19. Network-wide average of the hourly near-road PM<sub>2.5</sub> increment through 2017.**

Analyses of recent data indicate that, of the 25 CBSAs with valid design values<sup>30</sup> at the near-road site(s) from 2015 to 2017, 52% measured the highest annual design value at the near-

<sup>30</sup> A design value is considered valid if it meets the data handling requirements given in 40 CFR Appendix N to Part 50. Several large CBSAs such as Chicago-Naperville-Elgin, IL-IN-WI and Houston-The Woodlands-Sugar Land, TX had near-road sites that did not have valid PM<sub>2.5</sub> design values for the 2015-2017 period.

road site while 24% measured the highest 24-hour design value at the near-road site (Table 2-2). Of the CBSAs with highest annual design values at near-road sites, those design values were, on average, 0.7  $\mu\text{g}/\text{m}^3$  higher than at the highest measuring non-near-road sites (range is 0.1 to 2.0  $\mu\text{g}/\text{m}^3$  higher at near-road sites).

**Table 2-2. Daily and annual PM<sub>2.5</sub> design values for the near-road sites in major CBSAs (2015-2017).**

CBSA Name	Maximum Near-Road Daily Design Value	Maximum Non-Near-Road Daily Design Value	Maximum Near-Road Annual Design Value	Maximum Non-Near-Road Annual Design Value

Although most near-road monitoring sites do not have sufficient data to evaluate long-term trends in near-road PM<sub>2.5</sub> concentrations, analyses of the data at one near-road-like site in

Elizabeth, NJ,<sup>31</sup> show that the annual average increment has generally decreased between 1999 and 2017 from about 2.0  $\mu\text{g}/\text{m}^3$  to about 1.3  $\mu\text{g}/\text{m}^3$  (Figure 2-20). The trend in the near-road increment of elemental carbon at the Elizabeth, NJ site has shown a similar reduction, with values of  $\sim 1.0 \mu\text{g}/\text{m}^3$  in 2000 decreasing to  $\sim 0.5 \mu\text{g}/\text{m}^3$  in 2017. These data are consistent with the timing of EPA emission standards for motor vehicles.<sup>32</sup> Although long-term data are not available at other near-road sites, the national scope of the diesel vehicle controls suggests the near-road environment across the U.S. likely experienced similar decreasing trends in near-road  $\text{PM}_{2.5}$  increments.

**Figure 2-20. Annual average near-road increment for  $\text{PM}_{2.5}$  at the Elizabeth, NJ site.**

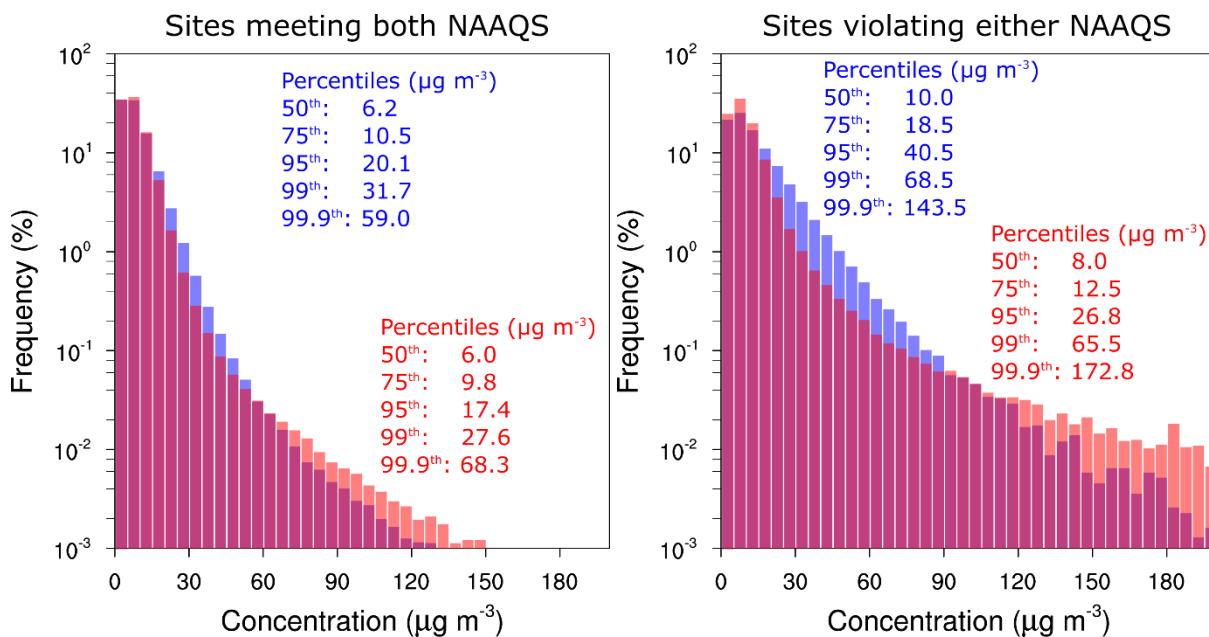

### 2.3.2.2.3 Sub-Daily Concentrations of $\text{PM}_{2.5}$

Ambient  $\text{PM}_{2.5}$  concentrations can exhibit a diurnal cycle that varies due to impacts from intermittent emission sources, meteorology, and atmospheric chemistry. The  $\text{PM}_{2.5}$  monitoring network in the U.S. has an increasing number of continuous FEM monitors reporting hourly  $\text{PM}_{2.5}$  mass concentrations that reflect this diurnal variation. The ISA describes a two-peaked diurnal pattern in urban areas, with morning peaks attributed to rush-hour traffic and afternoon peaks attributed to a combination of rush hour traffic, decreasing atmospheric dilution, and

<sup>31</sup> The Elizabeth Lab site in Elizabeth, NJ is situated approximately 30 meters from travel lanes of the Interchange 13 toll plaza of the New Jersey Turnpike and within 200 meters of travel lanes for Interstate 278 and the New Jersey Turnpike.

<sup>32</sup> See <https://www.epa.gov/diesel-fuel-standards/diesel-fuel-standards-and-rulemakings#nonroad-diesel>.

nucleation (U.S. EPA, 2019a, section 2.5.2.3, Figure 2-32). Because a focus on annual average and 24-hour average  $\text{PM}_{2.5}$  concentrations could mask sub-daily patterns, and because some health studies examine PM exposure durations shorter than 24-hours, it is useful to understand the broader distribution of sub-daily  $\text{PM}_{2.5}$  concentrations across the U.S. Figure 2-21 below presents the frequency distribution of 2-hour average  $\text{PM}_{2.5}$  mass concentrations from all FEM  $\text{PM}_{2.5}$  monitors in the U.S. for 2015-2017.<sup>33</sup> At sites meeting the current primary  $\text{PM}_{2.5}$  standards, these 2-hour concentrations generally remain below  $11 \mu\text{g}/\text{m}^3$ , and virtually never exceed  $32 \mu\text{g}/\text{m}^3$ . Two-hour concentrations are higher at sites violating the current standards, generally remaining below  $19 \mu\text{g}/\text{m}^3$  and virtually never exceeding  $69 \mu\text{g}/\text{m}^3$ .

**Figure 2-21. Frequency distribution of 2015-2017 2-hour averages for sites meeting both or violating either  $\text{PM}_{2.5}$  NAAQS for October to March (blue) and April to September (red).**

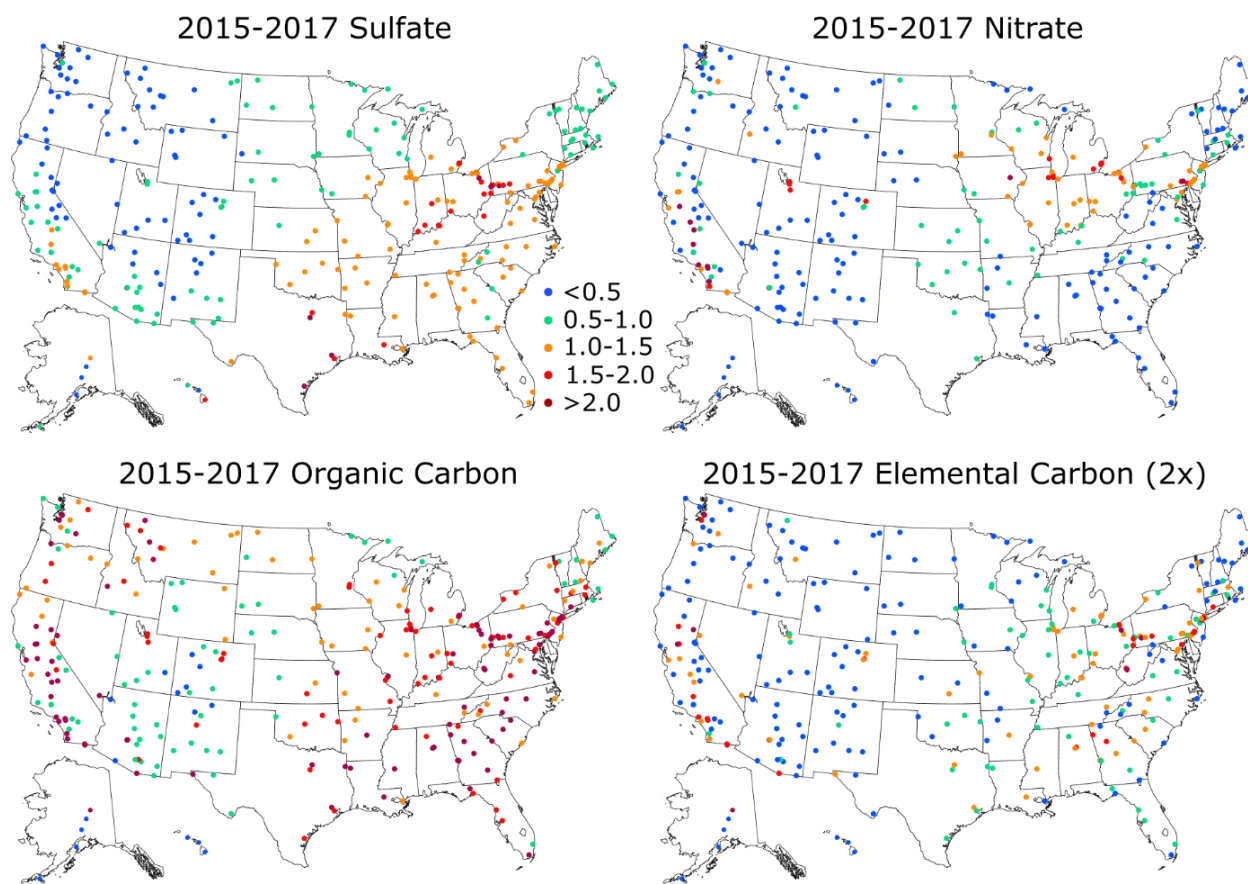

The extreme upper end of the distribution of 2-hour  $\text{PM}_{2.5}$  concentrations is shifted higher during the warmer months (red in Figure 2-21), generally corresponding to the period of peak wildfire frequency (April to September) in the U.S. At sites meeting the current primary standards, the highest 2-hour concentrations measured virtually never occur outside of the period of peak wildfire frequency. Most of the sites measuring these very high concentrations are in the northwestern U.S. and California, where wildfires have been relatively common in recent years

<sup>33</sup> As discussed further in section 3.2,  $\text{PM}_{2.5}$  controlled human exposure studies often examine 2-hour exposures. Thus, when evaluating those studies in the context of the current primary  $\text{PM}_{2.5}$  standards, it is useful to consider the distribution of 2-hour  $\text{PM}_{2.5}$  concentrations. Similar analyses of 5-hour  $\text{PM}_{2.5}$  concentrations are presented in Appendix A, Figure A-2.

(see Appendix A, Figure A-1). When the period of peak wildfire frequency is excluded from the analysis (blue in Figure 2-21), the extreme upper end of the distribution is reduced.

### 2.3.2.3 Chemical Composition of PM<sub>2.5</sub>

Based on recent air quality data, the major chemical components of PM<sub>2.5</sub> have distinct spatial distributions. Sulfate concentrations tend to be highest in the eastern U.S., while in the Ohio Valley, Salt Lake Valley, and California nitrate concentrations are highest and relatively high concentrations of organic carbon are widespread across most of the Continental U.S., as shown in Figure 2-22. Elemental carbon, crustal material, and sea-salt are found to have the highest concentrations in the northeast U.S., southwest U.S., and coastal areas, respectively.

**Figure 2-22. Annual average PM<sub>2.5</sub> sulfate, nitrate, organic carbon, and elemental carbon concentrations (in µg/m<sup>3</sup>) from 2015-2017.**

An examination of PM<sub>2.5</sub> composition trends can provide insight into the factors contributing to overall reductions in ambient PM<sub>2.5</sub> concentrations. The biggest change in PM<sub>2.5</sub> composition that has occurred in recent years is the reduction in sulfate concentrations due to reductions in SO<sub>2</sub> emissions. Between 2000 and 2015, the nationwide annual average sulfate concentration decreased by 17% at urban sites and 20% at rural sites. This change in sulfate

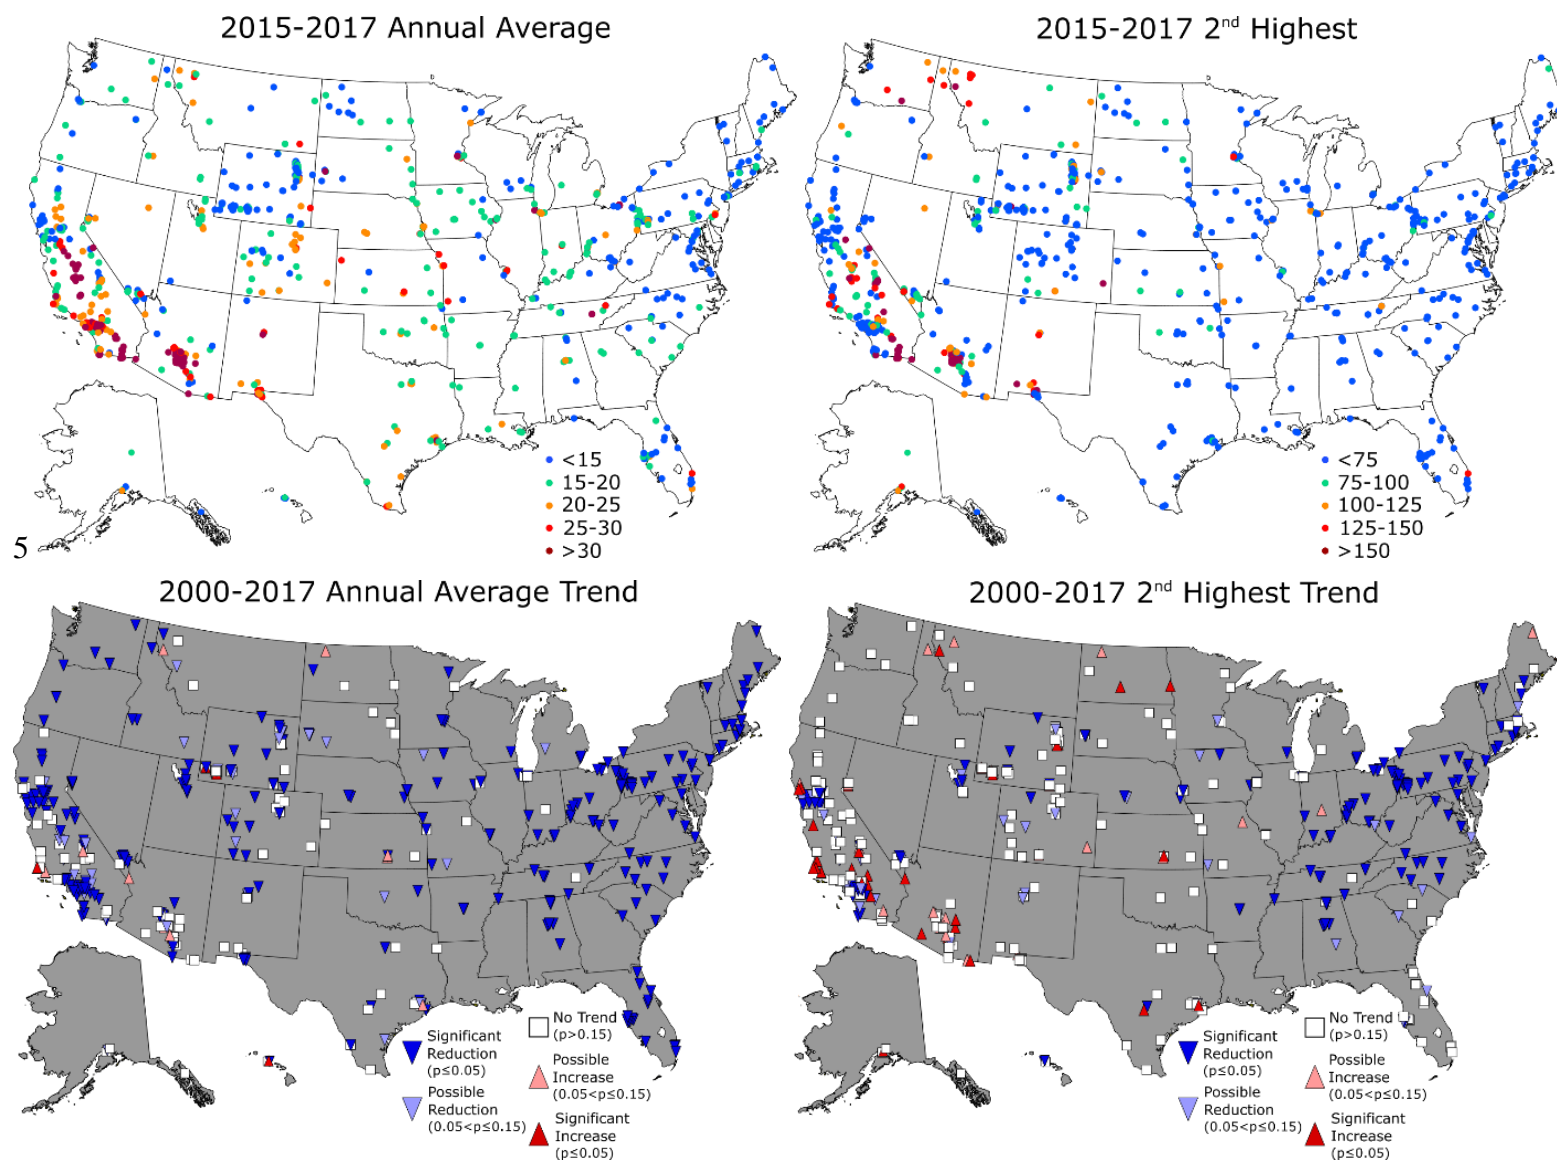

concentrations is most evident in the eastern U.S. and has resulted in organic matter or nitrate now being the greatest contributor to PM<sub>2.5</sub> mass in many locations (U.S. EPA, 2019a, Figure 2-19). The overall reduction in sulfate concentrations has contributed substantially to the decrease in national average PM<sub>2.5</sub> concentrations as well as the decline in the fraction of PM<sub>10</sub> mass accounted for by PM<sub>2.5</sub> (U.S. EPA, 2019a, section 2.5.1.1.6; section 2.3.1 above).

#### **2.3.2.4 National Characterization of PM<sub>10</sub> Mass**

At long-term monitoring sites in the U.S., the 2015-2017 average of 2<sup>nd</sup> highest 24-hour PM<sub>10</sub> concentration was 56 µg/m<sup>3</sup> (ranging from 18 to 173 µg/m<sup>3</sup>) (Figure 2-23, top panels).<sup>34</sup> The highest PM<sub>10</sub> concentrations tend to occur in the western U.S. Seasonal analyses indicate that ambient PM<sub>10</sub> concentrations are generally higher in the summer months than at other times of year, though the most extreme high concentration events are more likely in the spring (U.S. EPA, 2019a, Table 2-5). This is due to fact that the major PM<sub>10</sub> emission sources, dust and agriculture, are more active during the warmer and drier periods of the year.

---

<sup>34</sup> The form of the current 24-hour PM<sub>10</sub> standard is one-expected-exceedance, averaged over three years.

**Figure 2-23. Annual average and 2<sup>nd</sup> highest PM<sub>10</sub> concentrations (in  $\mu\text{g}/\text{m}^3$ ) from 2015-2017 (top) and linear trends and their associated significance in PM<sub>10</sub> concentrations from 2000-2017 (bottom).**

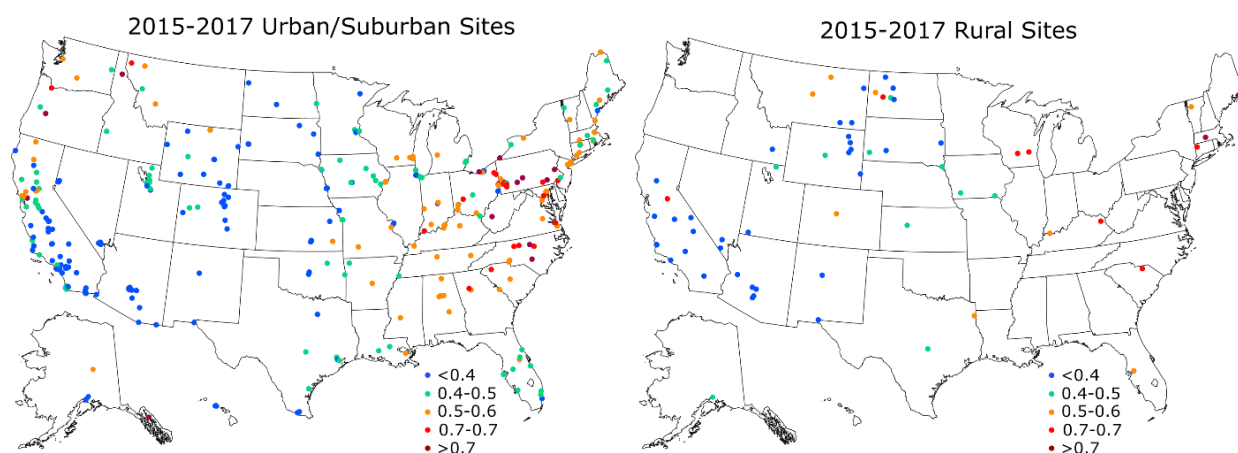

Recent ambient PM<sub>10</sub> concentrations reflect reductions that have occurred across much of the U.S. (Figure 2-23, bottom panels). From 2000 to 2017, 2<sup>nd</sup> highest 24-hour PM<sub>10</sub> concentrations have declined by about 30% (Figure 2-24).<sup>35</sup> Analyses at individual monitoring sites indicate that annual average PM<sub>10</sub> concentrations have declined at most sites across the U.S., with much of the decrease in the eastern U.S. associated with reductions in PM<sub>2.5</sub> concentrations. Annual second highest 24-hour PM<sub>10</sub> concentrations have generally declined in the eastern U.S., while concentrations in much of the midwest and western U.S. have remained unchanged or increased since 2000 (Figure 2-23, bottom panels).

**Figure 2-24. National trends in Annual 2<sup>nd</sup> Highest 24-Hour PM<sub>10</sub> concentrations from 2000 to 2017 (131 sites).** (Note: The white line indicates the mean concentration while the gray shading denotes the 10<sup>th</sup> and 90<sup>th</sup> percentile concentrations.)

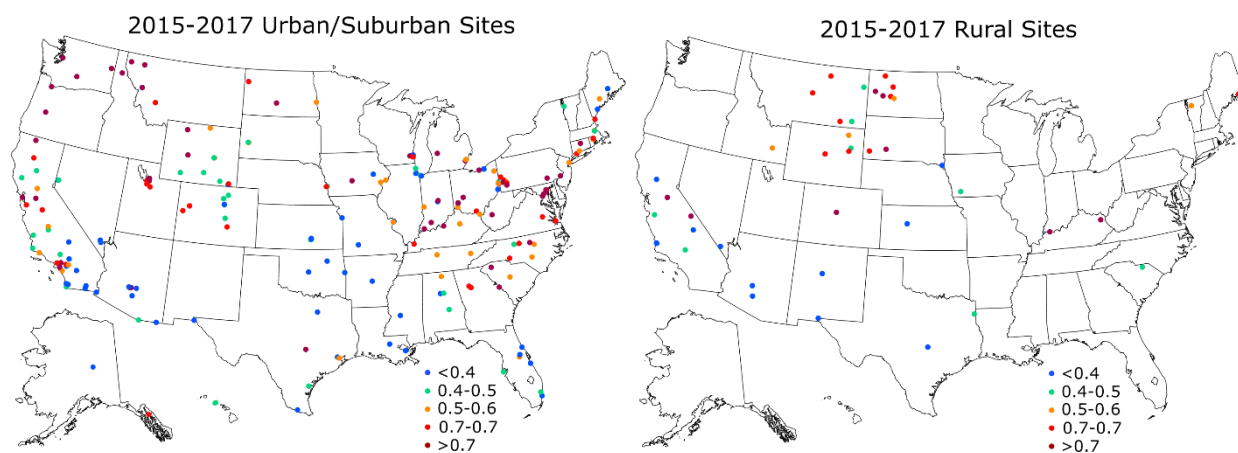

Compared to previous reviews, data available from the NCore monitoring network in the current review allows a more comprehensive analysis of the relative contributions of PM<sub>2.5</sub> and PM<sub>10-2.5</sub> to PM<sub>10</sub> mass. PM<sub>2.5</sub> generally contributes more to annual average PM<sub>10</sub> mass in the eastern U.S. than the western U.S. (Figure 2-25). At most sites in the eastern U.S., the majority of PM<sub>10</sub> mass is comprised of PM<sub>2.5</sub>. Similar east-west patterns are observed for both urban/suburban and rural sites. As ambient PM<sub>2.5</sub> concentrations have declined in the eastern U.S. (section 2.3.2.2, above), the ratios of PM<sub>2.5</sub> to PM<sub>10</sub> have also declined.

<sup>35</sup> For more information, see <https://www.epa.gov/air-trends/particulate-matter-pm10-trends#pmnat>.

**Figure 2-25. Annual average  $PM_{2.5}/PM_{10}$  ratio for 2015-2017.**

For days with very high  $PM_{10}$  concentrations (Figure 2-26), the  $PM_{2.5}/PM_{10}$  ratios are typically higher than the annual average ratios. This is particularly true in the northwestern U.S. where the high  $PM_{10}$  concentrations can occur during wildfires with high  $PM_{2.5}$ .

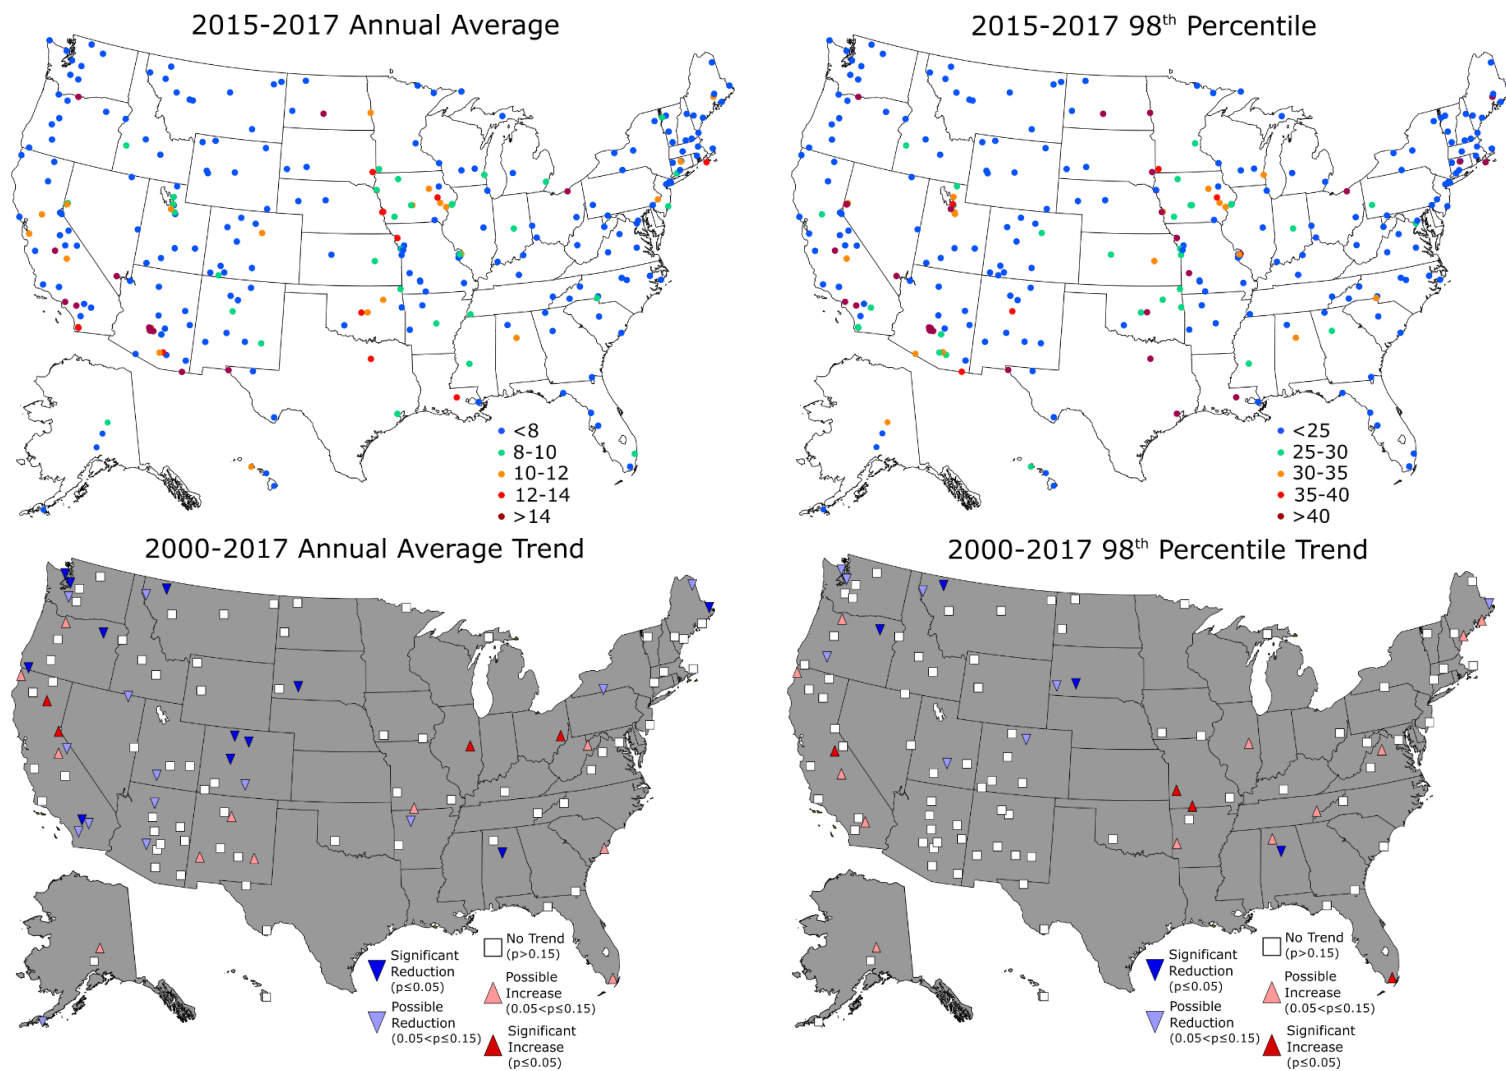

**Figure 2-26.  $PM_{2.5}/PM_{10}$  ratio for the second highest  $PM_{10}$  concentrations for 2015-2017.**

### 2.3.2.5 National Characterization of $PM_{10-2.5}$ Mass

Since the last review, the availability of  $PM_{10-2.5}$  ambient concentration data has greatly increased. As illustrated in Figure 2-27<sup>36</sup> (top panels), annual average and 98<sup>th</sup> percentile  $PM_{10-2.5}$  concentrations exhibit less distinct differences between the eastern and western U.S. than for either  $PM_{2.5}$  or  $PM_{10}$ . Additionally, compared to  $PM_{2.5}$  and  $PM_{10}$ , changes in  $PM_{10-2.5}$  concentrations have been small in magnitude and inconsistent in direction (Figure 2-27, lower panels).

<sup>36</sup> The sites shown in Figure 2-27 have a data completeness of either 75% or  $\geq 182$  valid days in each year.

**Figure 2-27. Annual average and 98<sup>th</sup> percentile PM<sub>10-2.5</sub> concentrations ( $\mu\text{g}/\text{m}^3$ ) from 2015-2017 (top) and linear trends and their associated significance in PM<sub>10-2.5</sub> concentrations from 2000-2017 (bottom).**

### 2.3.2.6 Characterization of the Ultrafine Fraction of PM<sub>2.5</sub> Mass

Compared to PM<sub>2.5</sub> mass, there is relatively little data on U.S. particle number concentrations, which are dominated by UFP. In the published literature, annual average particle number concentrations reaching about 20,000 to 30,000 cm<sup>-3</sup> have been reported in U.S. cities (U.S. EPA, 2019a). In addition, based on UFP measurements in two urban areas (New York City, Buffalo) and at a background site (Steuben County) in New York, there is a pronounced difference in particle number concentration between different types of locations (Figure 2-28; U.S. EPA, 2019a, Figure 2-18). Urban particle number counts were several times higher than at the background site, and the highest particle number counts in an urban area with multiple sites (Buffalo) were observed at a near-road location. Hourly data indicate that particle numbers remain fairly constant throughout the day at the background site, that they peak around 8:00 a.m. in Buffalo and New York City (NYC), and that they remain high into the evening hours with distinct rush hour and early afternoon peaks.

**Figure 2-28. Average hourly particle number concentrations from three locations in the State of New York for 2014 to 2015 (green is Steuben County, orange is Buffalo, red is New York City).** (Source: Figure 2-18 in U.S. EPA, 2019a).

Long-term trends in UFP are generally not available at U.S. monitoring sites. However, data on number size distribution have been reported for an 8-year period from 2002 to 2009 in Rochester, NY. Number concentrations averaged 4,730 cm<sup>-3</sup> for 0.01 to 0.05 µm particles and 1,838 cm<sup>-3</sup> for 0.05 to 0.1 µm particles (Wang et al., 2011). On average over the 8 years that UFP data were collected in Rochester, total particle number concentrations declined from the earlier period evaluated (i.e., 2001 to 2005) to the later period (2006 to 2009). This decline was

most evident for particles between 0.01 and 0.1  $\mu\text{m}$  and was attributed to changes in local sources resulting from the 2007 Heavy Duty Highway Rule, a reduction in local industrial activity, and the closure of a nearby coal-fired power plant (Wang et al., 2011; U.S. EPA, 2019a, section 2.5.2.1.4).

In addition, at a site in Illinois the annual average particle number concentration declined between 2000 and 2017, closely matching the reductions in annual  $\text{PM}_{2.5}$  mass over that same period (Figure 2-29, below). Particle number concentrations at this site are closer to those of the background site in Figure 2-28 than the urban sites. A recent study found that particle number concentrations in an urban area (Pittsburgh, PA) decreased between 2001-2002 and 2016-2017 along with decreases in  $\text{PM}_{2.5}$  associated with  $\text{SO}_2$  emission reductions (Saha et al., 2018). However, the relationship between changes in ambient  $\text{PM}_{2.5}$  and UFPs cannot be comprehensively characterized due to the high variability and limited monitoring of UFPs.

**Figure 2-29. Time series of annual average mass and number concentrations (left) and scatterplot of mass vs. number concentration (right) between 2000-2017 in Bondville, IL.**

### 2.3.3 Predicted Ambient $\text{PM}_{2.5}$ Based on Hybrid Modeling Approaches

Ambient concentrations of  $\text{PM}_{2.5}$  are often characterized using measurements from national monitoring networks due to the accuracy and precision of the measurements and the public availability of data. For applications requiring  $\text{PM}_{2.5}$  characterizations across urban areas, data averaging techniques such as area-wide and population-weighted averaging of monitors are sometimes used to provide complete coverage from the site measurements (U.S. EPA, 2019a, chapter 3). Yet data averaging methods may not adequately represent the spatial heterogeneity of

PM<sub>2.5</sub> within an area and are not practical for large unmonitored areas or time periods. As a result, additional methods have been developed to improve PM<sub>2.5</sub> characterizations in areas where monitoring is relatively sparse or unavailable. Methods include interpolation of monitored data, land-use regression models, chemical-transport models (CTMs), models based on satellite-derived aerosol optical depth (AOD), and hybrid spatiotemporal models that combine information from the individual approaches (U.S. EPA, 2019a, chapter 3). A number of recent studies have employed such methods to estimate PM<sub>2.5</sub> air quality concentrations across the U.S. and Canada, and to estimate population exposures for use in epidemiologic analyses (U.S. EPA, 2019a, sections 3.3 and 3.4). Given the increasing availability and application of these methods, in this section we provide an overview of recently developed hybrid modeling methods, their predictions and performance, and how predictions from various methods compare to each other.

#### **2.3.3.1.1 Overview of Hybrid Methods**

Hybrid methods are broadly classified into four categories: (1) methods based primarily on interpolation of monitor data, (2) Bayesian statistical downscalers, (3) methods based primarily on satellite-derived AOD, and (4) methods based on machine-learning algorithms. Each method is discussed briefly below.

Interpolation-based methods are the simplest approach for developing spatial fields of PM<sub>2.5</sub> concentrations and rely on the moderate degree of spatial autocorrelation in PM<sub>2.5</sub> in many areas of the U.S. Interpolation methods often use inverse-distance or inverse-distance-squared weighted averaging of monitoring data to predict PM<sub>2.5</sub> concentrations at unmonitored receptor points. Examples include the Voronoi neighbor averaging (VNA) approach and the enhanced VNA approach (eVNA). The VNA approach applies weighted averaging to the concentrations monitored in the Voronoi cells neighboring the cell containing the prediction point (Abt Associates, 2014). In the eVNA approach, monitored data are further weighted by the ratio of CTM predictions in the grid-cell containing the prediction point to the grid-cell containing the monitor (Abt Associates, 2014).

Bayesian statistical modeling has been used to calibrate CTM PM<sub>2.5</sub> predictions or satellite-derived AOD estimates to surface measurements (Berrocal et al., 2012; Wang et al., 2018b). This approach, commonly referred to as a Bayesian downscaler because it “downscales” grid-cell average values to points, first regresses the PM<sub>2.5</sub> predictions or AOD estimates on monitoring data. The resulting relationships are then used to develop a gridded PM<sub>2.5</sub> field from the CTM or AOD input field. Bayesian downscalers have been applied to develop gridded daily PM<sub>2.5</sub> fields at 12-km resolution for the conterminous U.S. (Wang et al., 2018b; U.S. EPA, 2017). An ensemble technique that optimally combines predictions of CTM and AOD

downscalers has also been developed to predict PM<sub>2.5</sub> at high resolution over Colorado during the fire season (Geng et al., 2018).

Surface PM<sub>2.5</sub> concentrations can also be predicted based on satellite retrievals of AOD and the relationship between surface PM<sub>2.5</sub> and AOD from CTM simulations (van Donkelaar et al., 2010). For example, in van Donkelaar et al. (2015a), satellite-based approaches (van Donkelaar et al., 2010; van Donkelaar et al., 2013) were used to estimate a gridded field of global mean PM<sub>2.5</sub> concentration for the 2001-2010 period that was combined with information from radiometrically stable satellite instruments (Boys et al., 2014) to develop global PM<sub>2.5</sub> fields over the 1998-2012 period (van Donkelaar et al., 2015a). Motivated by the limited use of surface measurements in this approach, van Donkelaar et al. (2015b) developed an updated method that incorporates additional information from PM<sub>2.5</sub> monitoring networks to improve performance. Specifically, geographically weighted regression (GWR) of residual PM<sub>2.5</sub> (i.e., the difference between monitored PM<sub>2.5</sub> and predictions based on satellite-derived AOD) with land-use and other variables is performed to improve PM<sub>2.5</sub> concentration estimates in areas such as North America where monitoring is relatively dense (van Donkelaar et al., 2019; van Donkelaar et al., 2015b). This approach has been used to create long-term PM<sub>2.5</sub> fields globally and for North America at about 1-km resolution. However, the developers caution that PM<sub>2.5</sub> gradients may not be fully resolved at 1-km resolution due to the influence of coarser-scale data used in the model<sup>37</sup> and report that mean error variance decreases when averaging the 1-km fields to coarser resolution (van Donkelaar et al., 2019).

Daily PM<sub>2.5</sub> fields based on non-parametric (i.e., machine learning) methods have also been developed to characterize PM<sub>2.5</sub> over the U.S. Non-parametric methods facilitate the use of large numbers of predictor variables that may have complex nonlinear relationships with PM<sub>2.5</sub> concentrations that would be challenging to specify with a parametric method. For example, a neural network algorithm was used to predict daily PM<sub>2.5</sub> fields at 1-km resolution over the conterminous U.S. during 2000-2012 using more than 50 predictor variables including satellite-derived AOD, CTM predictions, satellite-derived absorbing aerosol index, meteorological data, and land-use variables (Di et al., 2016). A random forest algorithm was also applied to develop daily PM<sub>2.5</sub> fields at 12-km resolution over the conterminous U.S. in 2011 and provide variable importance information for about 40 predictor variables including CTM results and satellite-derived AOD (Hu et al., 2017). Satellite-derived AOD and the convolution layer for nearby PM<sub>2.5</sub> measurements are ranked among the top five most important predictor variables for the importance metrics considered. A wide range of parametric and non-parametric hybrid PM<sub>2.5</sub> models have recently been reviewed in Chapter 3 of the ISA (U.S. EPA, 2019a).

---

<sup>37</sup> See [http://fizz.phys.dal.ca/~atmos/martin/?page\\_id=140](http://fizz.phys.dal.ca/~atmos/martin/?page_id=140)

### 2.3.3.1.2 Performance of the Methods

The performance of hybrid modeling methods is often evaluated against surface measurements using n-fold cross validation (i.e., 1/n of the data are reserved for validation with the rest used for model training, and the process is repeated n times). Although model evaluation methods are not consistent across studies, ten-fold cross-validation statistics are often reported and support use of the hybrid methods just described. For example, the neural network achieved total  $R^2$  of 0.84 and root-mean-square error (RMSE) of  $2.94 \mu\text{g m}^{-3}$  for daily  $\text{PM}_{2.5}$  predictions at sites in the conterminous U.S. during 2000-2012 (Di et al., 2016). The random forest achieved total  $R^2$  of 0.80 and RMSE of  $2.83 \mu\text{g m}^{-3}$  for daily  $\text{PM}_{2.5}$  predictions at U.S. sites in 2011 (Hu et al., 2017). The satellite-derived AOD approach with GWR yielded an  $R^2$  of 0.79 and RMSE of  $1.7 \mu\text{g m}^{-3}$  in cross validation for longer-term  $\text{PM}_{2.5}$  predictions at sites in North America (van Donkelaar et al., 2015b). The Bayesian downscalers had weaker performance in cross validation (e.g., national  $R^2$ : 0.66-0.70; Wang et al., 2018b; Kelly et al., 2019) than the other methods, possibly due to the relatively small number of predictor variables. However, the downscalers have advantages of simplicity, computational efficiency, and lower potential for overfitting compared with the machine learning methods.

Although model validation analyses often report favorable performance in terms of aggregate cross-validation statistics, studies have reported heterogeneity in performance by season, region, and concentration range. For example, several methods had relatively high cross-validation  $R^2$  in summer compared with other seasons (Kelly et al., 2019; Hu et al., 2017; Di et al., 2016; van Donkelaar et al., 2015b). Also, studies have noted relatively weak performance in parts of the western U.S., possibly due to the complex terrain, low concentrations (and therefore signal-to-noise ratio), less dense monitoring, prevalence of wildfire, and challenges in satellite retrievals and CTM modeling (Di et al., 2016; Wang et al., 2018b; Hu et al., 2017; Kelly et al., 2019). Predictive capability in terms of cross-validation  $R^2$  has also been reported to weaken with decreasing  $\text{PM}_{2.5}$  concentration in several studies (e.g., Kelly et al., 2019; Di et al., 2016; van Donkelaar et al., 2019). Trends in model performance associated with  $\text{PM}_{2.5}$  concentration (e.g., Figure 2-30) could be due in part to the relatively sparse monitoring in remote areas, where  $\text{PM}_{2.5}$  concentrations tend to be low. Consistent with this hypothesis, studies have reported degradation of model performance metrics with increasing distance to the nearest in-sample monitor, suggesting that predictions are most reliable in densely monitored urban areas (Jin et al., 2019; Huang et al., 2018; Kelly et al., 2019).

**Figure 2-30. R<sup>2</sup> for ten-fold cross-validation of daily PM<sub>2.5</sub> predictions in 2015 from three methods for individual sites as a function of observed concentration.** Text indicates the number of monitors in the PM<sub>2.5</sub> concentration range. Downscaler: Bayesian downscaler of CMAQ predictions; VNA: Voronoi Neighbor Averaging; eVNA: enhanced-VNA. From Kelly et al. (2019).

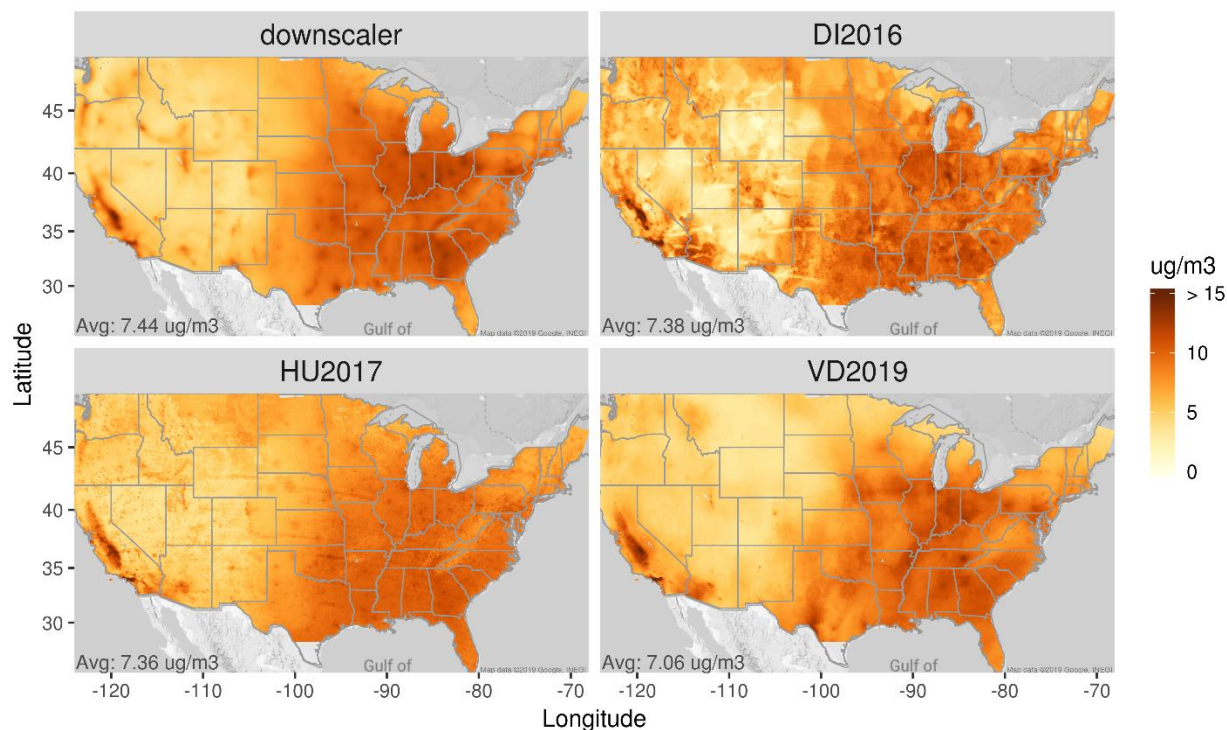

A limited number of studies have intercompared concentration predictions based on different PM<sub>2.5</sub> characterization methods. Huang et al. (2018) compared PM<sub>2.5</sub> concentrations from the method of Di et al., 2016 with concentrations from the CTM-based data fusion method of Friberg et al. (2016) and the satellite-derived AOD approach of Hu et al. (2014) for North Carolina. They reported general agreement in concentrations among methods, with some differences along the coast and in forested regions where monitoring is less dense. Yu et al. (2018) compared PM<sub>2.5</sub> concentrations from fourteen approaches of varying complexity for developing PM<sub>2.5</sub> spatial fields over the Atlanta, Georgia region. They reported that predictions of the methods can differ considerably, and the hybrid approaches that incorporate CTM predictions generally outperformed the simpler techniques (e.g., monitor interpolation). Also, model predictions appeared to be more reliable in the urban center based on relatively low cross validation R<sup>2</sup> for sites away from the urban core. Jin et al. (2019) reported increasing uncertainty in hybrid model predictions with distance to the nearest AQS monitor. Keller and Peng (2019) reported that a prediction model incorporating CTM output outperformed a monitor averaging approach and error reduction could be achieved by restricting the study to areas near monitors.

### 2.3.3.1.3 Comparison of PM<sub>2.5</sub> Fields Across Approaches

To illustrate features of the spatial fields reported in the literature, the annual mean PM<sub>2.5</sub> concentrations for 2011 from four methods is shown in Figure 2-31, where predictions from the methods were averaged to a common 12-km grid. The fields were developed using a Bayesian downscaler (downscaler, Berrocal et al., 2012), neural network (DI2016, Di et al., 2016), random forest (HU2017, Hu et al., 2017), and GWR of residuals from satellite-based PM<sub>2.5</sub> estimates (VD2019; van Donkelaar et al., 2019). Annual mean concentrations were developed from daily PM<sub>2.5</sub> predictions in the downscaler, DI2016, and HU2017 cases and from monthly PM<sub>2.5</sub> predictions in the VD2019 case. General features of the 2011 fields are in reasonable agreement

across methods, with elevated concentrations across broad areas of the eastern U.S. and in the San Joaquin Valley and South Coast Air Basin of California. The national mean PM<sub>2.5</sub> concentration for the VD2019 case (7.06  $\mu\text{g m}^{-3}$ ) is slightly lower than those of the other cases (7.36-7.44  $\mu\text{g m}^{-3}$ ), possibly because the VD2019 fields were developed using monthly (rather than daily) PM<sub>2.5</sub> measurements. Use of monthly averages provides greater influence on the annual mean of sites with less frequent monitoring that tend to be in rural areas with relatively low concentrations. Mean PM<sub>2.5</sub> concentrations predicted by the four methods in nine U.S. climate regions (Karl and Koss, 1984) are provided in Table 2-3.

**Figure 2-31. Comparison of 2011 annual average PM<sub>2.5</sub> concentrations from four methods.**  
(Note: These four methods include: downscaler (Berrocal et al., 2012), DI2016 (Di et al., 2016), HU2017 (Hu et al., 2017), and VD2019 (van Donkelaar et al., 2019). Predictions have been averaged to a common 12-km grid for this comparison.)

**Table 2-3. Mean 2011 PM<sub>2.5</sub> concentration by region for predictions in Figure 2-24**

Region <sup>1</sup>	downscaler	HU2017	DI2016	VD2019
Northeast	8.5	8.0	8.2	7.5
Southeast	9.9	10.0	9.4	9.8
Ohio Valley	10.7	9.6	9.8	10.0
Upper Midwest	8.8	7.9	7.9	7.1

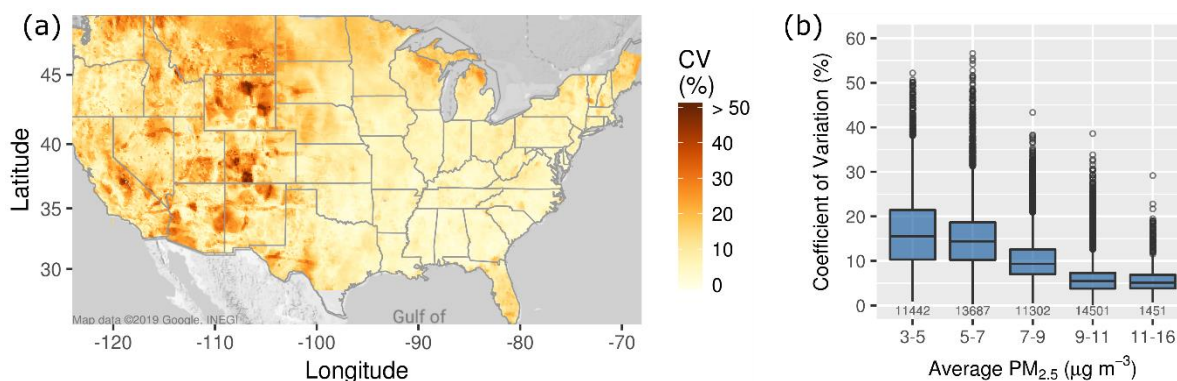

South	8.8	8.9	9.0	8.7
Southwest	5.0	5.3	5.2	5.1
N. Rockies & Plains	5.6	5.9	5.6	4.5
Northwest	5.0	5.3	6.1	4.9
West	5.5	5.7	6.0	6.5
<sup>1</sup> U.S. climate region: <a href="https://www.ncdc.noaa.gov/monitoring-references/maps/us-climate-regions.php">https://www.ncdc.noaa.gov/monitoring-references/maps/us-climate-regions.php</a> .				

In Figure 2-32, PM<sub>2.5</sub> concentrations predicted by the four methods are shown at their native resolution for regions centered on California, New Jersey, and Arizona. Predictions span a wider range of concentrations for the western regions centered on California and Arizona (Figure 2-32, panels a and c) than the eastern region centered on New Jersey (Figure 2-32, panel b). Despite general agreement among predictions for the California and the eastern U.S. areas, the spatial texture of the concentration fields differs among methods. For instance, the 12-km Bayesian downscaler produces the smoothest PM<sub>2.5</sub> concentration field, and the 1-km neural network (DI2016) produces the field with the greatest variance. Some of the largest differences in PM<sub>2.5</sub> concentration among methods occurred over southwest Arizona. The DI2016 and VD2019 methods predict higher concentrations in this area than the downscaler and HU2017 methods, and the DI2016 approach predicts distinct spatial features associated with Interstate 40, 10, and 8 that are not apparent in the other fields (Figure 2-32, panel c).

**Figure 2-32. Comparison of 2011 annual average PM<sub>2.5</sub> concentrations from four methods for regions centered on the (a) California (b) New Jersey, and (c) Arizona.** Predictions are shown at their native resolution (i.e., about 1-km for DI2016 and VD2019 and 12-km for downscaler and HU2017).

In Figure 2-33, the coefficient of variation (CV; i.e., the standard deviation divided by the mean) among methods is shown in percentage units based on predictions that were averaged to a common 12-km grid. The largest values occur in the western U.S. (Figure 2-33, panel a), where terrain is complex, wildfire is prevalent, monitoring is relatively sparse, and PM<sub>2.5</sub> concentrations tend to be low. The distance from the grid-cell center to the nearest monitor is greater than 100 km for broad areas of the west (Figure 2-34).

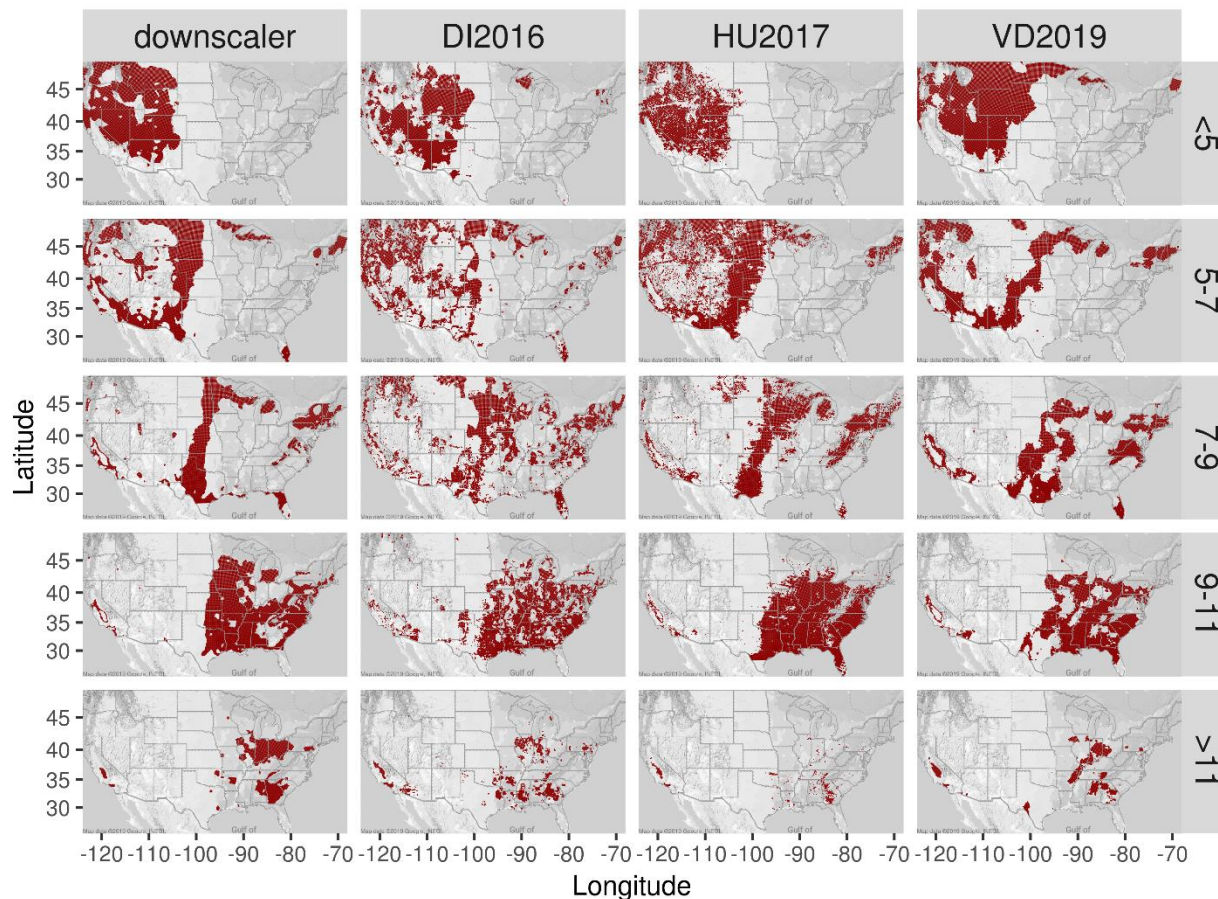

**Figure 2-33. (a) Spatial distribution of the CV (i.e., standard deviation divided by mean) in percentage units for the four models in Figure 2-31. (b) Boxplot distributions of CV for grid cells binned by the average  $\text{PM}_{2.5}$  concentration for the four models. (Note: The box brackets the interquartile range (IQR), the horizontal line within the box represents the median, the whiskers represent 1.5 times the IQR from either end of the box, and circles represent individual values less than and greater than the range of the whiskers.)**

**Figure 2-34. Distance from the center of the 12-km grid cells to the nearest  $\text{PM}_{2.5}$  monitoring site for  $\text{PM}_{2.5}$  measurements from the AQS database and IMPROVE network.**

Concentrations less than  $5 \mu\text{g m}^{-3}$  occur exclusively in the western U.S. for the downscaler and HU2017 methods, and the western U.S. plus a few areas along the northern U.S. border in the eastern U.S. for the DI2016 and VD2019 methods (Figure 2-35, top row). Concentrations between  $5$  and  $7 \mu\text{g m}^{-3}$  are predicted in the western U.S. and parts of New England for all methods and over Florida by the downscaler and DI2016 approaches (Figure 2-35, second row). The CV among methods increases with decreasing concentration (Figure 2-33 above, panel b), and the median CV is about 15% for grid cells with mean concentrations less than  $7 \mu\text{g m}^{-3}$ . As illustrated by Figure 2-33 and Figure 2-35, the low-concentration areas with

relatively large CVs are in the western U.S. and along the northern and southern border of the eastern U.S.

**Figure 2-35. Location of PM<sub>2.5</sub> predictions by range in annual average concentration for the four prediction methods at their native resolution.** (Note: Concentration ranges: < 5 µg/m<sup>3</sup>, 5-7 µg/m<sup>3</sup>, 7-9 µg/m<sup>3</sup>, 9-11 µg/m<sup>3</sup>, and >11 µg/m<sup>3</sup>.)

The comparison of PM<sub>2.5</sub> concentrations across approaches was based on the 2011 period due to the availability of predictions from multiple methods for that year. As discussed earlier in this chapter, PM<sub>2.5</sub> concentrations have declined over the U.S. in the last several decades. Annual mean PM<sub>2.5</sub> concentrations predicted by the VD2019 method for 2011 are compared with predictions for 2001, 2006, and 2016 in Figure 2-36. The VD2019 fields capture the trend of decreasing PM<sub>2.5</sub> over the U.S. during this period, and the areas with annual mean PM<sub>2.5</sub> concentration greater than 11 µg m<sup>-3</sup> in 2016 are limited to California and southwest Arizona.

**Figure 2-36. Annual mean PM<sub>2.5</sub> from the VD2019 method (van Donkelaar et al., 2019) for 2001, 2006, 2011, and 2016.**

#### 2.3.3.1.4 Summary

Hybrid PM<sub>2.5</sub> modeling methods have improved the ability to estimate PM<sub>2.5</sub> exposure for populations throughout the conterminous U.S. compared with the earlier approaches based on monitoring data alone. Excellent performance in cross-validation tests suggests that hybrid methods are reliable for estimating PM<sub>2.5</sub> exposure in many applications. As discussed in Chapter 3 of this PA, good agreement in health study results between monitor- and model-based methods for urban areas (McGuinn et al., 2017) and general consistency in results for the conterminous U.S. (Jerrett et al., 2017; Di et al., 2016) also suggests that the fields are reliable for use in health studies. However, there are also important limitations associated with the modeled fields. First, performance evaluations for the methods are weighted toward densely monitored urban areas at the scales of representation of the monitoring networks. Predictions at different scales or in sparsely monitored areas are relatively untested. Second, studies have reported heterogeneity in performance with relatively weak performance in parts of the western U.S., at low concentrations, at greater distance to monitors, and under conditions where the reliability and availability of key input datasets (e.g., satellite retrievals and air quality modeling) are limited. Differences in predictions among different hybrid methods have also been reported and tend to be most important under conditions with the performance issues just noted. Differences in predictions could also be related to the different approaches used to create long-term PM<sub>2.5</sub> fields (e.g., averaging daily PM<sub>2.5</sub> fields vs. developing long-term average fields), which is important due to variable monitoring schedules. More work on comprehensively characterizing the performance of modeled fields is warranted and will further inform our understanding of the implications of using these fields to estimate PM<sub>2.5</sub> exposures in health studies.

## 2.4 BACKGROUND PM

For the purposes of this assessment, we define background PM as all particles that are formed by sources or processes that cannot be influenced by actions within the jurisdiction of concern. For this document, U.S. background PM is defined as any PM formed from emissions

other than U.S. anthropogenic (i.e. manmade) emissions. Potential sources of U.S. background PM include both natural sources (i.e. PM that would exist in the absence of any anthropogenic emissions of PM or PM precursors) and transboundary sources originating outside U.S. borders.

Ambient monitoring networks provide long-term records of speciated PM concentrations across the U.S., which can inform estimates of individual source contributions to background PM levels in different parts of the country. However, even the most remote monitors within the U.S. can be periodically affected by U.S. anthropogenic emissions. Monitor data are also limited in more remote areas due to a sparser monitoring network where PM concentrations are more likely influenced by background sources. Chemical transport models (CTMs) offer complementary information to ambient monitor networks by providing more spatially and temporally comprehensive estimates of atmospheric composition. CTMs can also be applied to isolate contributions from specific emission sources to PM concentrations in different areas via source apportionment or “zero-out” modeling (i.e., estimating what the residual concentrations would be were emissions from the emission source of interest to be entirely removed).

At annual and national scales, estimated background PM concentrations in the U.S. are small compared to contributions from domestic anthropogenic emissions. For example, based on zero-out modeling in the last review of the PM NAAQS, annual background PM<sub>2.5</sub> concentrations were estimated to range from 0.5 - 3  $\mu\text{g}/\text{m}^3$  across the sites examined. The magnitude and sources of background PM can vary widely by region and time of year. Coastal sites may experience a consistent contribution of PM from sea spray aerosol, while other areas covered with dense vegetation may be impacted by biogenic aerosol production during the summertime. Sources of background PM also operate across a range of time scales. While some sources like biogenic aerosol vary at monthly to seasonal scales, many sources of background PM are episodic in nature. These episodic sources (e.g. large wildfires) can be characterized by infrequent contributions to high-concentration events occurring over shorter periods of time (e.g., hours to several days). Such episodic events are sporadic and do not necessarily occur in all years. While these exceptional episodes can lead to violations of the daily PM<sub>2.5</sub> standard (35  $\mu\text{g}/\text{m}^3$ ) in some cases (Schweizer et al., 2017), such events are routinely screened for and usually identifiable in the monitoring data. As described further below, contributions to background PM in the U.S. result mainly from sources within North America. Contributions from intercontinental events have also been documented (e.g., transport from dust storms occurring in deserts in North Africa and Asia), but these events are less common and represent a relatively small fraction of background PM in most places.

While the potential sources of background PM discussed above include sources of both fine (PM<sub>2.5</sub>) and coarse (PM<sub>10</sub>) particles, background contributions to ambient UFP are less well characterized and are not discussed here due to lack of information. Section 2.4.1 below further

discusses background PM from natural sources inside the U.S. Section 2.4.2 characterizes the role of international transport of PM from sources outside U.S. borders.

#### **2.4.1 Natural Sources**

As noted in section 2.1.1, sources that contribute to natural background PM include dust from the wind erosion of natural surfaces, sea salt, wildland fires, primary biological aerosol particles (PBAP) such as bacteria and pollen, oxidation of biogenic hydrocarbons such as isoprene and terpenes to produce SOA, and geogenic sources such as sulfate formed from volcanic production of SO<sub>2</sub> and oceanic production of dimethyl-sulfide (DMS). While most of the above sources release or contribute predominantly to fine aerosol, some sources including windblown dust, and sea salt also produce particles in the coarse size range (U.S. EPA, 2019a, section 2.3.3).

Biogenic emissions from plants are perhaps the most ubiquitous sources of background PM in the U.S. Certain species of plants and trees can release large amounts of VOCs such as isoprene and monoterpenes that are oxidized in the atmosphere to form organic aerosol. SOA production from biogenic emissions is largest in the southeastern U.S., where conditions are warm, humid, and sunny for much of the year. Many of the processes involved with biogenic SOA formation are complex and remain highly uncertain. Results from radiocarbon techniques applied to distinguish modern (biogenic or fires) from fossil (anthropogenic) carbon fractions in organic aerosol have suggested comparable contributions from both carbon types in the Southeast where SOA concentrations are high (Schichtel et al., 2008). However, SOA formation from biogenic emission sources can also be facilitated by the presence of anthropogenic precursors (Xu et al., 2015). More work characterizing the interactions of anthropogenic and biogenic emissions is needed to determine the implications of such processes for background PM concentrations.

Soil dust and sea salt have been estimated to account for less than 10% of urban PM<sub>2.5</sub> on average in the U.S. (Karagulian et al., 2015), although episodic contributions from these sources can be much higher in some locations. For example, during a dust storm affecting Phoenix in July of 2011, peak hourly average PM<sub>10</sub> concentrations were greater than 5,000 µg/m<sup>3</sup>, with area-wide average hourly concentrations ranging from a few hundred to a few thousand µg/m<sup>3</sup> (Vukovic et al., 2014). Dust can also account for much of the PM that originates from outside the U.S., which we discuss further below (U.S. EPA, 2019a, section 2.5.4.2). In addition to sea salt aerosol, biological production of the sulfate precursor DMS can also occur in some marine environments, although the impact of DMS emissions on annual mean sulfate concentrations is likely very small in the U.S. (<0.2 µg/m<sup>3</sup>) and confined to coastal areas (Sarwar et al., 2018).

Wildfires release large amounts of particles and gaseous PM precursors. Invasive species, historical fire management practices, frequency of drought, and extreme heat have resulted in longer fire seasons (Jolly et al., 2015) and more large fires (Dennison et al., 2014) over time. In addition to emissions from fires in the U.S., emissions from fires in other countries can be transported to the U.S. Transport of smoke from fires in Canada, Mexico, Central America, and Siberia have been documented in multiple studies (U.S. EPA, 2009). According to the NEI, wildfire smoke contributes between 10 and 20% of primary PM emissions in the U.S. per year (U.S. EPA, 2019a, section 2.3.1), with much higher localized contributions near fire-affected areas.

To illustrate how episodic impacts from a large natural source can affect PM concentrations in the U.S., Figure 2-37 and Figure 2-38 show an example from a recent wildfire event. In summer 2017, smoke from wildfires in British Columbia, Canada led to severe air quality degradation in parts of the Pacific Northwest. A NASA Worldview<sup>38</sup> image from August 4, 2017 (Figure 2-37) shows smoke from multiple fire detections across southern British Columbia crossing into northern Washington state. Smoke from these fires was also captured at the North Cascades IMPROVE monitor (Figure 2-38), where daily fine PM concentrations were increased from a typical baseline of less than  $10 \mu\text{g}/\text{m}^3$  to  $\sim 100 \mu\text{g}/\text{m}^3$  during this time.

**Figure 2-37. Smoke and fire detections observed by the MODIS instrument onboard the Aqua satellite on August 4<sup>th</sup>, 2017 accessed through NASA Worldview.**

<sup>38</sup> Available from <https://worldview.earthdata.nasa.gov>.

**Figure 2-38. Fine PM mass time series during 2017 from the North Cascades IMPROVE site in north central Washington state.<sup>39</sup>**

Later in August and September 2017, many other wildfires occurred in Washington state and Oregon, making this fire season one of the worst for the Pacific Northwest in recent history. The severe fires in British Columbia, Washington and Oregon during 2017 have been linked to the combination of usually hot temperatures in August/September in the region following a very wet preceding winter season. While many of the most severe wildfire events in the U.S. occur in the western part of the country during the late summer, most of the contiguous U.S. is affected by wildfire smoke during some part of the year (Kaulfus et al., 2017).

## 2.4.2 International Transport

Background PM contributions from international sources include PM that is both natural and anthropogenic in origin crossing into U.S. borders from Canada and Mexico or from longer range intercontinental transport. While in general the biggest contributions to U.S. background PM from international sources come from nearby Canada and Mexico, large episodic events from intercontinental sources can sometimes occur (e.g., windblown dust from Asia or Africa). This section discusses transboundary PM transport within North America (section 2.4.2.1) as well as long range intercontinental transport from anthropogenic (section 2.4.2.2) and natural (section 2.4.2.3) sources.

<sup>39</sup> Available at [http://views.cira.colostate.edu/fed/SiteBrowser/Default.aspx?appkey=SBCF\\_PmHazeComp](http://views.cira.colostate.edu/fed/SiteBrowser/Default.aspx?appkey=SBCF_PmHazeComp).

#### **2.4.2.1 Transboundary Transport in North America**

As discussed above, some of the largest potential international sources of U.S. background PM originate elsewhere in North America. PM produced from fires in both Canada and Mexico can affect air quality in the U.S., particularly in border states (Park et al., 2007; Miller et al., 2011; Wang et al., 2018a). Anthropogenic emissions from Canada and Mexico can also influence U.S. PM air quality. An inverse modeling study by Henze et al. (2009) estimated that in 2001 anthropogenic SO<sub>x</sub> emissions from Canada and Mexico accounted for 6% and 4% respectively of total daily inorganic PM<sub>2.5</sub> in the U.S. These authors also estimated that SO<sub>x</sub> emissions related to international shipping accounted for approximately 2% of total inorganic PM in the U.S.

#### **2.4.2.2 Long Range Transport from Anthropogenic Sources**

Due to the relatively short atmospheric lifetime of particles (~days to weeks), long range transport of aerosols does not contribute significant PM mass to the U.S. Heald et al. (2006) estimated that transport from Asia accounted for less than 0.2 µg/m<sup>3</sup> of sulfate PM<sub>2.5</sub> in the Northwestern U.S. in spring, and Leibensperger et al. (2011) estimated intercontinental contributions from Asian anthropogenic SO<sub>2</sub> and NO<sub>x</sub> emissions of 0.1 - 0.25 µg/m<sup>3</sup> annually in the western U.S. Leibensperger et al. (2011) also concluded that much of the intercontinental influence captured by the GEOS-Chem model was in fact local PM production attributable to domestic emissions in receptor countries arising from changes in global oxidant budgets, rather than impacts from PM directly transported across geopolitical boundaries. The studies above are also consistent with findings from other analyses. A report from the United Nations on global air quality synthesizing results across many studies estimated an annual average contribution of approximately 0.1 µg/m<sup>3</sup> sulfate PM in North America due to transport from East Asia (TFHTAP, 2006).

#### **2.4.2.3 Long Range Transport from Natural Sources**

Long range transport of dust from both Asia (Vancuren and Cahill, 2002; Yu et al., 2008) and North Africa (Prospero, 1999a; Prospero, 1999b; Chiapello et al., 2005; McKendry et al., 2007) has been shown to occasionally contribute to surface PM concentrations in some regions of the U.S. The likelihood of such long-range dust transport events depends on large-scale meteorological patterns, which can vary significantly across seasons and between years. Yu et al. (2015) found that the transport of North African dust across the Atlantic Ocean is strongly negatively correlated with precipitation in the Sahel during the preceding year. Dust from Africa has also shown a decreasing trend of approximately 10% per decade from 1982 to 2008 based on measurements of aerosol optical depth and surface concentrations in Barbados. This trend was attributed to a corresponding decrease in surface winds over source regions (Ridley et al., 2014).

Variability in springtime Asian dust transport to the U.S. has been linked to north-south shifts in trans-Pacific flow modulated by the El Nino-Southern Oscillation (Achakulwisut et al., 2017), as well as to variations in regional precipitation affecting both dust emissions in Asia and atmospheric residence times during transport (Fischer et al., 2009).

On average, intercontinental dust transport is estimated to contribute about 1-2  $\mu\text{g}/\text{m}^3$  to annual  $\text{PM}_{2.5}$  at some U.S. sites (Jaffe et al., 2005; TFHTAP, 2006; Creamean et al., 2014). However, daily concentrations can be substantially larger for individual events, especially for coarser particles. For example, Jaffe et al. (2003) found evidence of Asian dust events in 1998 and 2001 contributing 30-40  $\mu\text{g}/\text{m}^3$  to daily  $\text{PM}_{10}$  at sites throughout the U.S., although the authors also note that large events of this scale are rare and only occurred twice during their 15-year study period. Similar magnitudes have also been reported for individual North African events; analysis of a multidecadal record of African dust reaching Miami indicated concentrations of PM ranging from ~10 to 120  $\mu\text{g}/\text{m}^3$  (Prospero, 1999b; Prospero, 1999a).<sup>40</sup>

### 2.4.3 Estimating Background PM with Recent Data

As discussed above, the 2009 PM ISA estimated background PM concentrations at several remote IMPROVE sites in different regions of the U.S. for 2004 using a combination of monitor data and zero-out air quality modeling. Revisiting the speciated IMPROVE PM data that the monitors included in the last assessment provides some insights into how contributions from different PM sources may have changed, and what those changes (or lack thereof) mean for our current understanding of background PM in the U.S.

Figure 2-39 shows observed annual average  $\text{PM}_{2.5}$  in 2004 and 2016 at the same remote monitors examined in the last ISA. The comparisons show decreases in both total  $\text{PM}_{2.5}$  and ammonium sulfate across all sites examined, consistent with decreases in anthropogenic  $\text{SO}_2$  and other PM precursors observed over this time period. It is likely that most of the remaining ammonium sulfate observed at these sites is also a result of domestic anthropogenic emissions and therefore not relevant for assessments of background PM.

Sea salt and dust aerosol are likely natural in origin at these remote sites. With the exception of REDW1, a coastal site in California, soil and sea salt aerosol together account for less than about 0.5  $\mu\text{g}/\text{m}^3$  of the annual average  $\text{PM}_{2.5}$  at all monitors examined here, which is below the values cited from the literature for long range dust contributions discussed above. Contributions from ammonium nitrate and elemental carbon could be from either anthropogenic or natural sources, but together represent less than about 0.5  $\mu\text{g}/\text{m}^3$  at most of the sites in 2016.

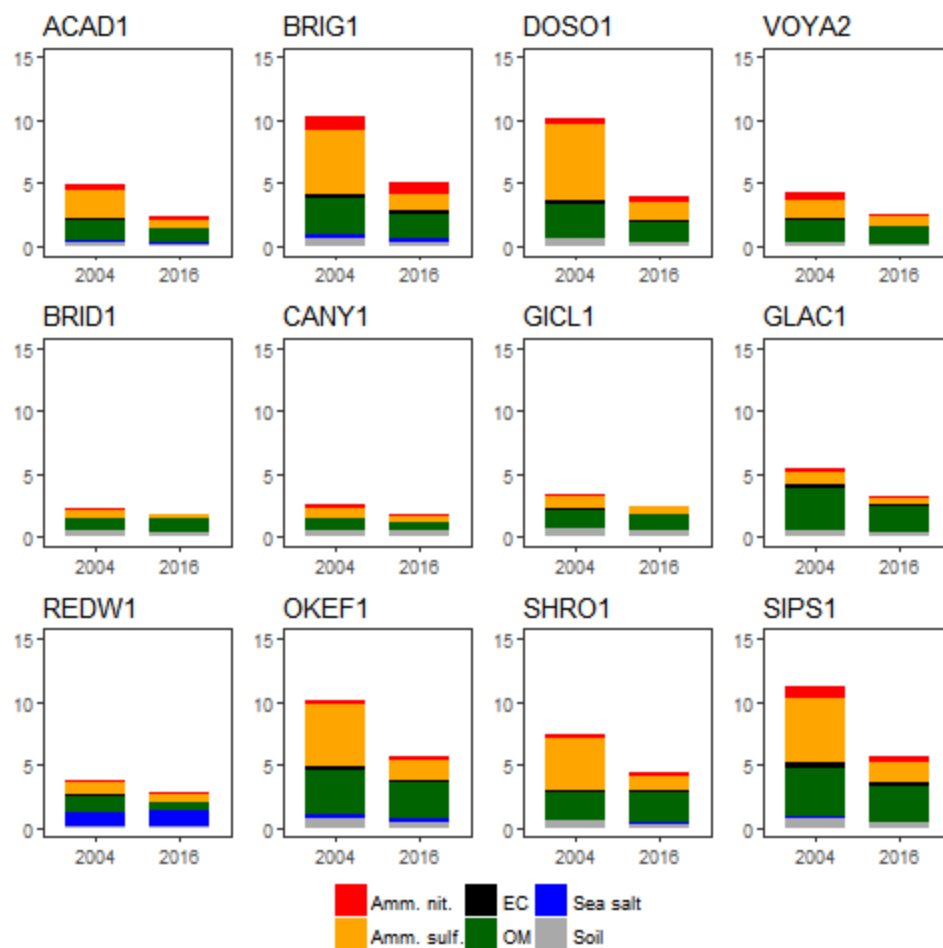

---

<sup>40</sup> Sample collection began in 1974, before network  $\text{PM}_{10}$  and  $\text{PM}_{2.5}$  samplers were developed, and no size cut was specified (Prospero, 1999b).

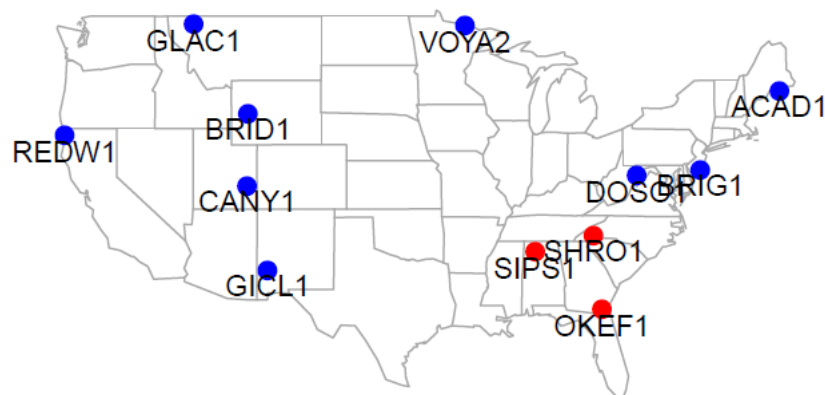

The largest contribution from nitrate occurs at the BRIG1 monitor in New Jersey and is likely anthropogenic given the high density of NO<sub>x</sub> from vehicle emissions in that region.

After ammonium sulfate, the next largest contributing species for most of the sites is organic matter, which for many of the monitors in Figure 2-39 represents 50% or more of total PM in both 2004 and 2016. In addition to the IMPROVE sites from the last ISA, Figure 2-31 also shows comparisons for three sites in the Southeast U.S. As a region, the Southeast has the highest levels of biogenic aerosol production in the country, so the organic matter contribution at these three sites likely represents an upper bound for the country of what natural biogenic organic aerosol production could be under present atmospheric conditions. The organic aerosol components shown in Figure 2-39 will also include the influence of fires for some monitors. The highest organic matter contribution for any of the sites shown in Figure 2-39, including the three Southeast monitors, is approximately 2 µg/m<sup>3</sup>. While contributions from ammonium sulfate have decreased substantially at some of the monitors, particularly the eastern sites, contributions from organic aerosol are roughly consistent between 2004 and 2016, as are the contributions from the other species assumed to be mostly natural in origin (soil and sea salt). Therefore, while no new zero-out modeling was done for the current review, revisiting these monitors with more recent data suggests that estimates of background concentrations at these monitors are still around 1-3 µg/m<sup>3</sup> and have not changed significantly since the last PM NAAQS Review.

While estimates of total annual background concentrations have generally not changed significantly since the last review, our scientific understanding of organic aerosol formation has evolved. Organic aerosol can be produced from a variety of natural and anthropogenic processes, which presents a challenge for source attribution techniques. Additionally, new research over the past decade has identified a host of new sources and chemical pathways for SOA formation that have only recently begun to be implemented into CTMs. Further research implementing these new sources and pathways into CTMs is needed to understand 1) the behavior of these different algorithms under a range of possible atmospheric conditions, and 2) what the implications are for understanding SOA formation in the U.S.

### 3 REVIEW OF THE PRIMARY STANDARDS FOR PM<sub>2.5</sub>

This chapter presents our key policy-relevant considerations and conclusions regarding the public health protection provided by the current suite of primary PM<sub>2.5</sub> standards and the protection that could be provided by potential alternative standards. These considerations and conclusions are framed by a series of policy-relevant questions, including the following overarching questions:

- **Does the currently available scientific evidence, air quality and quantitative risk information support or call into question the adequacy of the public health protection afforded by the current annual and 24-hour PM<sub>2.5</sub> standards?**
- **What range of potential alternative standards could be supported by the available scientific evidence, air quality and risk information?**

The answers to these questions are informed by our evaluation of a series of more specific policy-relevant questions, which expand upon those presented at the outset of this review in the IRP (U.S. EPA, 2016). Answers to these questions are intended to inform decisions by the Administrator on whether, and if so how, to revise the current suite of primary fine particle standards.

Section 3.1 presents our approach for reviewing the primary standards for PM<sub>2.5</sub>. Sections 3.2 and 3.3 present our consideration of the available scientific evidence and our consideration of information from the PM<sub>2.5</sub> risk assessment, respectively. Section 3.4 summarizes CASAC advice and public comments and section 3.5 summarizes our conclusions regarding the adequacy of the public health protection provided by the current primary PM<sub>2.5</sub> standards and the protection that could be provided by potential alternative standards. Section 3.6 discusses areas for future research and data collection to improve our understanding of fine particle-related health effects in future reviews.

#### 3.1 APPROACH

##### 3.1.1 Approach Used in the Last Review

The last review of the primary PM NAAQS was completed in 2012 (78 FR 3086, January 15, 2013). As noted above (section 1.3), in the last review the EPA lowered the level of the primary annual PM<sub>2.5</sub> standard from 15.0 to 12.0 µg/m<sup>3</sup>,<sup>1</sup> and retained the existing 24-hour PM<sub>2.5</sub> standard with its level of 35 µg/m<sup>3</sup>. The 2012 decision to strengthen the suite of primary PM<sub>2.5</sub>

---

<sup>1</sup> The Agency also eliminated spatial averaging provisions as part of the form of the annual standard.

standards was based on the Administrator's consideration of the extensive body of scientific evidence assessed in the 2009 ISA (U.S. EPA, 2009); the quantitative risk analyses presented in the 2010 HREA (U.S. EPA, 2010);<sup>2</sup> the advice and recommendations of the CASAC (e.g., Samet, 2009; Samet, 2010c; Samet, 2010b); and public comments on the proposed rule (78 FR 3086, January 15, 2013; U.S. EPA, 2012). The Administrator particularly noted the "strong and generally robust body of evidence of serious health effects associated with both long- and short-term exposures to PM<sub>2.5</sub>" (78 FR 3120, January 15, 2013). This included epidemiologic studies reporting health effect associations based on long-term average PM<sub>2.5</sub> concentrations ranging from about 15.0 µg/m<sup>3</sup> or above (i.e., at or above the level of the then-existing annual standard) to concentrations "significantly below the level of the annual standard" (78 FR 3120, January 15, 2013). The Administrator further observed that such studies were part of an overall pattern across a broad range of studies reporting positive associations, which were frequently statistically significant. Based on her "confidence in the association between exposure to PM<sub>2.5</sub> and serious public health effects, combined with evidence of such an association in areas that would meet the current standards" (78 FR 3120, January 15, 2013), the Administrator concluded that revision of the suite of primary PM<sub>2.5</sub> standards was necessary in order to provide increased public health protection. Specifically, she concluded that the then-existing suite of primary PM<sub>2.5</sub> standards was not sufficient, and thus not requisite, to protect public health with an adequate margin of safety. This decision was consistent with advice received from the CASAC (Samet, 2010c).

The Administrator next considered what specific revisions to the existing primary PM<sub>2.5</sub> standards were appropriate, given the available evidence and quantitative risk information. She considered both the annual and 24-hour PM<sub>2.5</sub> standards, focusing on the basic elements of those standards (i.e., indicator, averaging time, form, and level). These considerations, and the Administrator's conclusions, are summarized in sections 3.1.1.1 to 3.1.1.4 below.

#### **3.1.1.1 Indicator**

In initially setting standards for fine particles in 1997, the EPA concluded it was appropriate to control fine particles as a group, based on PM<sub>2.5</sub> mass, rather than singling out any particular component or class of fine particles (62 FR 38667, July 18, 1997). In the review completed in 2006, based on similar considerations, the EPA concluded that the available information supported retaining the PM<sub>2.5</sub> indicator and remained too limited to support a distinct

---

<sup>2</sup> In the last review, the EPA generated a quantitative health risk assessment for PM, and did not conduct a microenvironmental exposure assessment (U.S. EPA, 2010). To be consistent with our general process for reviewing the NAAQS (section 1.2, above), and with our discussion of potential quantitative analyses in the current review, we refer to the 2010 health risk assessment as the 2010 HREA.

standard for any specific PM<sub>2.5</sub> component or group of components associated with particular source categories of fine particles (71 FR 61162 to 61164, October 17, 2006).

In the last review, the EPA again considered issues related to the appropriate indicator for fine particles, with a focus on evaluating support for the existing PM<sub>2.5</sub> mass-based indicator and for potential alternative indicators based on the ultrafine particle fraction or on fine particle composition (78 FR 3121, January 15, 2013).<sup>3</sup> With regard to PM<sub>2.5</sub> mass, as in the 1997 and 2006 reviews, the health studies available during the last review continued to link adverse health outcomes (e.g., premature mortality, hospital admissions, emergency department visits) with long- and short-term exposures to fine particles indexed largely by PM<sub>2.5</sub> mass (78 FR 3121, January 15, 2013). With regard to the ultrafine fraction of ambient PM, the PA noted the limited body of health evidence assessed in the ISA (summarized in U.S. EPA, 2009, section 2.3.5 and Table 2–6) and the limited monitoring information available to characterize ambient concentrations of ultrafine particles (U.S. EPA, 2011, section 1.3.2). With regard to PM composition, the ISA concluded that “the evidence is not yet sufficient to allow differentiation of those constituents or sources that are more closely related to specific health outcomes” (U.S. EPA, 2009, pp. 2-26 and 6-212; 78 FR 3123, January 15, 2013). The PA further noted that “many different constituents of the fine particle mixture as well as groups of components associated with specific source categories of fine particles are linked to adverse health effects” (U.S. EPA, 2011, p. 2–55; 78 FR 3123, January 15, 2013). Consistent with the considerations and conclusions in the PA, the CASAC advised that it was appropriate to consider retaining PM<sub>2.5</sub> as the indicator for fine particles. The CASAC specifically stated that “[t]here [is] insufficient peer-reviewed literature to support any other indicator at this time” (Samet, 2010a, p. 12). In light of the evidence and the CASAC’s advice, the Administrator concluded that it was “appropriate to retain PM<sub>2.5</sub> as the indicator for fine particles” (78 FR 3123, January 15, 2013).

### **3.1.1.2 Averaging Time**

In 1997, the EPA set an annual PM<sub>2.5</sub> standard to provide protection from health effects associated with long- and short-term exposures to PM<sub>2.5</sub>, and a 24-hour standard to supplement the protection afforded by the annual standard (62 FR 38667 to 38668, July, 18, 1997). In the 2006 review, the EPA retained both annual and 24-hour averaging times (71 FR 61164, October 17, 2006).

In the last review, the EPA again considered issues related to the appropriate averaging times for PM<sub>2.5</sub> standards, with a focus on evaluating support for the existing annual and 24-hour

---

<sup>3</sup> In the last review, the ISA defined ultrafine particles as generally including particles with a mobility diameter less than or equal to 0.1 µm. Mobility diameter is defined as the diameter of a particle having the same diffusivity or electrical mobility in air as the particle of interest, and is often used to characterize particles of 0.5 µm or smaller (U.S. EPA, 2009, pp. 3-2 to 3-3).

averaging times and for potential alternative averaging times based on sub-daily or seasonal metrics. Based on the evidence assessed in the ISA, the PA noted that the overwhelming majority of studies that had been conducted since the 2006 review continued to utilize annual (or multi-year) or 24-hour PM averaging periods (U.S. EPA, 2011, section 2.3.2). With regard to potential support for an averaging time shorter than 24-hours, the PA noted that studies of cardiovascular effects associated with sub-daily PM concentrations had evaluated a variety of PM metrics (e.g., PM<sub>2.5</sub>, PM<sub>10</sub>, PM<sub>10-2.5</sub>, ultrafine particles), averaging periods (e.g., 1, 2, and 4 hours), and health outcomes (U.S. EPA, 2011, section 2.3.2). The PA concluded that this evidence, when viewed as a whole, was too uncertain to serve as a basis for establishing a primary PM<sub>2.5</sub> standard with an averaging time shorter than 24-hours (U.S. EPA, 2011, p. 2-57).<sup>4</sup> With regard to potential support for a seasonal averaging time, few studies were available to deduce a general pattern in PM<sub>2.5</sub>-related risk across seasons, and these studies did not provide information on health effects associated with season-long exposures to PM<sub>2.5</sub> (U.S. EPA, 2011, p. 2-58; 78 FR 3124, January 15, 2013).

The PA reached the overall conclusions that the available information provided strong support for considering retaining the current annual and 24-hour averaging times and did not provide support for considering alternative averaging times (U.S. EPA, 2011, p. 2-58). The CASAC agreed that these conclusions were reasonable (Samet, 2010a, p. 13). The Administrator concurred with the PA conclusions and with the CASAC's advice. Specifically, she judged that it was "appropriate to retain the current annual and 24-hour averaging times for the primary PM<sub>2.5</sub> standards to protect against health effects associated with long- and short-term exposure periods" (78 FR 3124, January 15, 2013).

### **3.1.1.3 Form**

In 1997, the EPA established the form of the annual PM<sub>2.5</sub> standard as an annual arithmetic mean, averaged over 3 years, from single or multiple community-oriented monitors.<sup>5</sup> That is, the level of the annual standard was to be compared to measurements made at each community-oriented monitoring site or, if specific criteria were met, measurements from multiple community-oriented monitoring sites could be averaged together (i.e., spatial

---

<sup>4</sup> For respiratory effects specifically, the Administrator further noted the ISA conclusion that the strongest associations were observed with 24-hour average or longer exposures, not with exposures less than 24-hours (U.S. EPA, 2009, section 6.3).

<sup>5</sup> As noted above (section 1.3), in the last review the EPA replaced the term "community-oriented" monitor with the term "area-wide" monitor. *Area-wide* monitors are those sited at the neighborhood scale or larger, as well as those monitors sited at micro- or middle scales that are representative of many such locations in the same core-based statistical area (CBSA; 78 FR 3236, January 15, 2013). CBSAs are required to have at least one area-wide monitor sited in the area of expected maximum PM<sub>2.5</sub> concentration.

averaging)<sup>6</sup> (62 FR 38671 to 38672, July 18, 1997). In the 1997 review, the EPA also established the form of the 24-hour PM<sub>2.5</sub> standard as the 98<sup>th</sup> percentile of 24-hour concentrations at each monitor within an area (i.e., no spatial averaging), averaged over three years (62 FR at 38671 to 38674, July 18, 1997). In the 2006 review, the EPA retained these standard forms but tightened the criteria for using spatial averaging with the annual standard (71 FR 61167, October 17, 2006).<sup>7</sup>

In the last review, the EPA's consideration of the form of the annual PM<sub>2.5</sub> standard again included a focus on the issue of spatial averaging. An analysis of air quality and population demographic information indicated that the highest PM<sub>2.5</sub> concentrations in a given area tended to be measured at monitors in locations where the surrounding populations were more likely to live below the poverty line and to include larger percentages of racial and ethnic minorities (U.S. EPA, 2011, p. 2-60). Based on this analysis, the PA concluded that spatial averaging could result in disproportionate impacts in at-risk populations, including minority populations and populations with lower socioeconomic status (SES). Therefore, the PA concluded that it was appropriate to consider revising the form of the annual PM<sub>2.5</sub> standard such that it did not allow for the use of spatial averaging across monitors (U.S. EPA, 2011, p. 2-60). The CASAC agreed with the PA conclusions that it was "reasonable" for the EPA to eliminate the spatial averaging provisions (Samet, 2010c, p. 2), stating the following: "Given mounting evidence showing that persons with lower SES levels are a susceptible group for PM-related health risks, [the] CASAC recommends that the provisions that allow for spatial averaging across monitors be eliminated" (Samet, 2010a, p. 13).

The Administrator concluded that public health would not be protected with an adequate margin of safety in all locations, as required by law, if disproportionately higher PM<sub>2.5</sub> concentrations in low income and minority communities were averaged together with lower concentrations measured at other sites in a large urban area. Therefore, she concluded that the form of the annual PM<sub>2.5</sub> standard should be revised to eliminate spatial averaging provisions (78 FR 3124, January 15, 2013). Thus, the level of the annual PM<sub>2.5</sub> standard established in the last review is to be compared with measurements from each appropriate monitor in an area, with no allowance for spatial averaging.

---

<sup>6</sup> The original criteria for spatial averaging included: (1) the annual mean concentration at each site shall be within 20% of the spatially averaged annual mean, and (2) the daily values for each monitoring site pair shall yield a correlation coefficient of at least 0.6 for each calendar quarter (62 FR 38671 to 38672, July 18, 1997).

<sup>7</sup> Specifically, the Administrator revised spatial averaging criteria such that "(1) [t]he annual mean concentration at each site shall be within 10 percent of the spatially averaged annual mean, and (2) the daily values for each monitoring site pair shall yield a correlation coefficient of at least 0.9 for each calendar quarter (71 FR 61167, October 17, 2006).

In the last review, the EPA also considered the form of the 24-hour PM<sub>2.5</sub> standard. The Agency recognized that the existing 98<sup>th</sup> percentile form for the 24-hour standard was originally selected to provide a balance between limiting the occurrence of peak 24-hour PM<sub>2.5</sub> concentrations and identifying a stable target for risk management programs.<sup>8</sup> Updated air quality analyses in the last review provided additional support for the increased stability of the 98<sup>th</sup> percentile PM<sub>2.5</sub> concentration, compared to the 99<sup>th</sup> percentile (U.S. EPA, 2011, Figure 2-2, p. 2-62). Consistent with the PA conclusions based on this analysis, the Administrator concluded that it was appropriate to retain the 98<sup>th</sup> percentile form for the 24-hour PM<sub>2.5</sub> standard (78 FR 3127, January 15, 2013).

#### **3.1.1.4 Level**

The EPA's approach to considering alternative levels of the PM<sub>2.5</sub> standards in the last review was based on evaluating the public health protection afforded by the annual and 24-hour standards, taken together, against mortality and morbidity effects associated with long-term or short-term PM<sub>2.5</sub> exposures. This approach recognized that there is no bright line clearly directing the choice of level. Rather, the choice of what is appropriate is a public health policy judgment entrusted to the Administrator. In the last review, this judgment included consideration of the strengths and limitations of the evidence and the appropriate inferences to be drawn from the evidence and the risk assessments.

In evaluating alternative standards, the Agency considered the extent to which potential alternative annual and 24-hour standard levels would be expected to reduce the mortality and morbidity risks associated with both long-term and short-term PM<sub>2.5</sub> exposures. Results of the 2010 HREA indicated that, compared to revising the 24-hour standard level, lowering the level of the annual standard would result in more consistent risk reductions across urban study areas, thereby potentially providing a more consistent degree of public health protection across the U.S. (U.S. EPA, 2010, pp. 5-15 to 5-17; 78 FR 3128, January 15, 2013). Based on risk results, together with the available evidence, the Administrator concluded that it was appropriate to lower the level of the annual standard in order to increase protection against both long- and short-term PM<sub>2.5</sub> exposures. She further concluded that it was appropriate to retain the 24-hour standard in order to provide supplemental protection, particularly for areas with high peak-to-mean ratios of 24-hour PM<sub>2.5</sub> concentrations (e.g., areas with important local or seasonal sources) and for PM<sub>2.5</sub>-related effects that may be associated with shorter-than daily exposure periods. The Administrator judged that this approach was the "most effective and efficient way to reduce

---

<sup>8</sup> See *ATA III*, 283 F.3d at 374–376 which concludes that it is legitimate for the EPA to consider overall stability of the standard and its resulting promotion of overall effectiveness of NAAQS control programs in setting a standard that is requisite to protect the public health.

total PM<sub>2.5</sub>-related population risk and to protect public health with an adequate margin of safety” (78 FR 3158, January 15, 2013).

In selecting the level of the annual PM<sub>2.5</sub> standard, the Administrator recognized the substantial increase in the number and diversity of studies available in the last review, including extended analyses of seminal studies of long-term PM<sub>2.5</sub> exposures (i.e., American Cancer Society (ACS) and Harvard Six Cities studies), important new long-term exposure studies, and new U.S. multi-city epidemiologic studies that greatly expanded and reinforced our understanding of mortality and morbidity effects associated with short-term PM<sub>2.5</sub> exposures. She placed the greatest emphasis on health endpoints for which the evidence was strongest, based on the assessment of the evidence in the ISA and on the ISA’s causality determinations (U.S. EPA, 2009, section 2.3.1). She particularly noted that the evidence was sufficient to conclude a causal relationship exists between PM<sub>2.5</sub> exposures and mortality and cardiovascular effects (i.e., for both long- and short-term exposures) and that the evidence was sufficient to conclude a causal relationship is “likely” to exist between PM<sub>2.5</sub> exposures and respiratory effects (i.e., for both long- and short-term exposures). The Administrator also noted additional, but more limited, evidence for a broader range of health endpoints, including evidence “suggestive of a causal relationship” between long-term exposures and developmental and reproductive effects as well as carcinogenic effects (78 FR 3158, January 15, 2013).

Based on information discussed and presented in the ISA, the Administrator recognized that health effects may occur over the full range of ambient PM<sub>2.5</sub> concentrations observed in epidemiologic studies, since no discernible population-level threshold could be identified based on the evidence available in the last review (78 FR 3158, January 15, 2013; U.S. EPA, 2009, section 2.4.3). To inform her decisions on an appropriate level for the annual standard in the absence of a discernible population-level threshold, the Administrator considered the degree to which epidemiologic studies indicate confidence in the reported health effect associations over distributions of ambient PM<sub>2.5</sub> concentrations. In doing so, she recognized that epidemiologic studies provide greater confidence in the observed associations for the part of the air quality distribution corresponding to the bulk of the health events evaluated, generally at and around the long-term mean PM<sub>2.5</sub> concentrations. Accordingly, the Administrator weighed most heavily the long-term mean concentrations reported in key multi-city epidemiologic studies. She also took into account additional population-level information from a subset of studies, beyond the long-term mean concentrations, to identify a broader range of PM<sub>2.5</sub> concentrations to consider in

judging the need for public health protection.<sup>9</sup> In doing so, the Administrator recognized that studies indicate diminished confidence in the magnitude and significance of observed associations in the lower part of the air quality distribution, corresponding to where a relatively small proportion of the health events are observed.

In revising the level of the annual standard to  $12.0 \mu\text{g}/\text{m}^3$ , the Administrator noted that such a level was below the long-term mean  $\text{PM}_{2.5}$  concentrations reported in key epidemiologic studies that provided evidence of an array of serious health effects, including premature mortality and increased hospitalizations for cardiovascular and respiratory effects (78 FR 3161, January 15, 2013). The Administrator further noted that  $12.0 \mu\text{g}/\text{m}^3$  generally corresponded to the lower portions (i.e., about the 25<sup>th</sup> percentile) of distributions of health events in the limited number of epidemiologic studies for which population-level information was available. The Administrator viewed this population information as helpful in guiding her determination as to where her confidence in the magnitude and significance of the  $\text{PM}_{2.5}$  associations were reduced to such a degree that a standard set at a lower level was not warranted. The Administrator also recognized that a level of  $12.0 \mu\text{g}/\text{m}^3$  reflected placing some weight on studies of reproductive and developmental effects, for which the evidence was more uncertain (78 FR 3161-3162, January 15, 2013).<sup>10</sup>

In conjunction with a revised annual standard with a level of  $12.0 \mu\text{g}/\text{m}^3$ , the Administrator concluded that the evidence supported retaining the  $35 \mu\text{g}/\text{m}^3$  level of the 24-hour  $\text{PM}_{2.5}$  standard. Specifically, she judged that by lowering the level of the annual standard, the distribution of 24-hour  $\text{PM}_{2.5}$  concentrations would be lowered as well, affording additional protection against effects associated with short-term  $\text{PM}_{2.5}$  exposures.<sup>11</sup> She noted that the existing 24-hour standard, with its  $35 \mu\text{g}/\text{m}^3$  level and 98<sup>th</sup> percentile form, would provide supplemental protection, particularly for areas with high peak-to-mean ratios possibly associated with strong local or seasonal sources and for areas with  $\text{PM}_{2.5}$ -related effects that may be associated with shorter than daily exposure periods (78 FR 3163, January 15, 2013).

---

<sup>9</sup> This information characterized the distribution of health events in the studies, and the corresponding long-term mean  $\text{PM}_{2.5}$  concentrations (78 FR 3130 to 3134, January 15, 2013). The additional population-level data helped inform the Administrator's judgment of how far below the long-term mean concentrations to set the level of the annual standard (78 FR 3160).

<sup>10</sup> With respect to cancer, mutagenic, and genotoxic effects, the Administrator observed that the  $\text{PM}_{2.5}$  concentrations reported in studies evaluating these effects generally included ambient concentrations that are equal to or greater than ambient concentrations observed in studies that reported mortality and cardiovascular and respiratory effects (U.S. EPA, 2009, section 7.5). Therefore, the Administrator concluded that, in selecting a standard level that provides protection from mortality and cardiovascular and respiratory effects, it is reasonable to anticipate that protection will also be provided for carcinogenic effects (78 FR 3161-3162, January 15, 2013).

<sup>11</sup> This judgment is supported by risk results presented in the 2010 HREA. For example, see section 4.2.2, and Figures 4-4 and 4-6 (U.S. EPA, 2010).

The Administrator recognized that uncertainties remained in the scientific information. She specifically noted uncertainties related to understanding the relative toxicity of the different components in the fine particle mixture, the role of PM<sub>2.5</sub> in the complex ambient mixture, exposure measurement errors in epidemiologic studies, and the nature and magnitude of estimated risks related to relatively low ambient PM<sub>2.5</sub> concentrations. Furthermore, the Administrator noted that epidemiologic studies had reported heterogeneity in responses both within and between cities and in geographic regions across the U.S. She recognized that this heterogeneity may be attributed, in part, to differences in fine particle composition in different regions and cities. With regard to evidence for reproductive and developmental effects, the Administrator recognized that there were a number of limitations associated with this body of evidence, including the following: the limited number of studies evaluating such effects; uncertainties related to identifying the relevant exposure time periods of concern; and limited toxicological evidence providing little information on the mode of action(s) or biological plausibility for an association between long-term PM<sub>2.5</sub> exposures and adverse birth outcomes.

On balance, the Administrator found that the available evidence, interpreted in light of the remaining uncertainties (noted above), did not justify an annual standard level set below 12.0 µg/m<sup>3</sup> as being “requisite” (i.e., neither more nor less stringent than necessary) to protect public health with an adequate margin of safety. Thus, the Administrator concluded that the available evidence and information supported an annual standard with a level of 12.0 µg/m<sup>3</sup>, combined with a 24-hour standard with a level of 35 µg/m<sup>3</sup>. She noted that this combination of standard levels was consistent with the CASAC’s advice to consider an annual standard level within the range of 13 to 11 µg/m<sup>3</sup> and a 24-hour standard level from 35 to 30 µg/m<sup>3</sup> (Samet, 2010c). Taken together, the Administrator concluded that the revised annual PM<sub>2.5</sub> standard, with its level of 12.0 µg/m<sup>3</sup> and a form that does not allow for spatial averaging, combined with the existing 24-hour standard, would be requisite to protect the public health with an adequate margin of safety from effects associated with long- and short-term PM<sub>2.5</sub> exposures.

### **3.1.2 General Approach in the Current Review**

The approach for this review builds on the substantial body of work completed during the last review, taking into account the more recent scientific information and air quality data now available to inform our understanding of the key policy-relevant issues. The approach summarized below is most fundamentally based on using the EPA’s assessment of the current scientific evidence for health effects attributable to fine particle exposures (i.e., in the ISA, U.S. EPA, 2019), along with quantitative assessments of PM<sub>2.5</sub>-associated health risks and analyses of PM<sub>2.5</sub> air quality, and CASAC advice, to inform the Administrator’s judgments regarding the primary standards for fine particles that are requisite to protect the public health with an adequate

margin of safety. In this PA, we seek to provide as broad an array of policy options as is supportable by the available scientific and technical information, recognizing that the selection of a specific approach to reaching final decisions on the primary PM<sub>2.5</sub> standards will reflect the judgments of the Administrator as to what weight to place on the various types of information and associated uncertainties.

In considering the public health protection provided by the current primary PM<sub>2.5</sub> standards, and the protection that could be provided by alternatives, we emphasize health outcomes for which the ISA determines that the evidence supports either a “causal” or a “likely to be causal” relationship with PM<sub>2.5</sub> exposures (U.S. EPA, 2019). We consider the PM<sub>2.5</sub>-related health effects documented in studies that support these causality determinations and, together with other analyses (i.e., air quality analyses, risk assessment), what they may indicate regarding the primary PM<sub>2.5</sub> standards. In doing so, we specifically focus on information from key epidemiologic and controlled human exposure studies.

Epidemiologic studies represent a large part of the evidence base supporting several of the ISA’s “causal” and “likely to be causal” determinations. As discussed below in section 3.2.3.2, the use of information from epidemiologic studies to inform conclusions on the primary PM<sub>2.5</sub> standards is complicated by the fact that such studies evaluate associations between distributions of ambient PM<sub>2.5</sub> and health outcomes and do not identify the specific exposures that cause reported effects. Rather, health effects can occur over the entire distributions of ambient PM<sub>2.5</sub> concentrations evaluated, and epidemiologic studies do not identify a population-level threshold below which it can be concluded with confidence that PM-associated health effects do not occur (U.S. EPA, 2019, section 1.5.3). In the absence of a discernible threshold, we use two approaches to consider information from epidemiologic studies (section 3.2.3.2).

In one approach, we evaluate the PM<sub>2.5</sub> air quality distributions over which epidemiologic studies support health effect associations and the degree to which such distributions are likely to occur in areas meeting the current (or alternative) standards. As discussed further in section 3.2.3.2.1, epidemiologic studies generally provide the strongest support for reported health effect associations over the part of the air quality distribution corresponding to the bulk of the underlying data (i.e., estimated exposures and/or health events), often falling in the middle part of the distribution (i.e., rather than at the extreme upper or lower ends). In support of this, a number of epidemiologic studies report that confidence intervals around concentration-response functions are relatively narrow around the overall means of the PM<sub>2.5</sub> concentrations examined and wider at the extreme upper and lower ends of the distributions. The observed narrowing of confidence intervals over the middle portions of these distributions likely reflects the relatively large amount of data available (i.e., the numerous “typical” daily or annual PM<sub>2.5</sub> exposures estimated). As described in greater detail in section 3.2.3.2.1, in using PM<sub>2.5</sub> air quality data from

epidemiologic studies to inform conclusions on standards we evaluate study-reported means (or medians) of daily and annual average PM<sub>2.5</sub> concentrations as proxies for the middle portions of the air quality distributions that support reported associations. When data are available, we also consider the broader PM<sub>2.5</sub> air quality distributions around the overall mean concentrations, with a focus on the lower quartiles of data, to provide insight into the concentrations below which data supporting reported associations become relatively sparse.

A key uncertainty in using study-reported PM<sub>2.5</sub> concentrations to inform conclusions on the primary PM<sub>2.5</sub> standards is that they reflect the averages of daily or annual PM<sub>2.5</sub> air quality concentrations or exposure estimates in the study population over the years examined by the study, and are not the same as the PM<sub>2.5</sub> design values used by the EPA to determine whether areas meet the NAAQS (section 3.2.3.2.1).<sup>12</sup> Therefore, as described in section 3.2.3.2.2, in this review we also consider a second approach to evaluating information from epidemiologic studies. In this approach, we calculate study area air quality metrics similar to PM<sub>2.5</sub> design values (i.e., referred to in this PA as “pseudo-design values”) and consider the degree to which such metrics indicate that study area air quality would likely have met or violated the current or alternative standards during study periods. When pseudo-design values in individual study locations are linked with the populations living in those locations, or with the number of study-specific health events recorded in those locations, these values can provide insight into the degree to which reported health effect associations are based on air quality likely to have met or violated the current (or alternative) primary PM<sub>2.5</sub> standards.

To the extent the application of these two approaches indicates that health effect associations are based on PM<sub>2.5</sub> air quality likely to have met the current or alternative standards, those standards are likely to allow the daily or annual average PM<sub>2.5</sub> exposures that provide the foundation for reported associations. Alternatively, to the extent reported health effect associations reflect air quality violating the current or alternative standards, there is greater uncertainty in the degree to which those standards would allow the PM<sub>2.5</sub> exposures that provide the foundation for reported associations. Sections 3.2.3.2.1 and 3.2.3.2.2 discuss each of these approaches in detail, and present our key observations based on their application.

Beyond epidemiologic studies, we additionally consider what controlled human exposure studies may indicate regarding the current and alternative primary PM<sub>2.5</sub> standards. Controlled human exposure studies examine short-term PM<sub>2.5</sub> exposures (i.e., up to several hours) under

---

<sup>12</sup> The design value is a statistic that describes the air quality status of a given area relative to the NAAQS. As discussed further in section 3.2.3.2.1, to determine whether areas meet or violate the NAAQS, the EPA measures air pollution concentrations at individual monitors (i.e., concentrations are not averaged across monitors) and calculates design values at monitors meeting appropriate data quality and completeness criteria. For an area to meet the NAAQS, all valid design values in that area, including the highest annual and 24-hour monitored values, must be at or below the levels of the standards.

carefully controlled laboratory conditions. Drawing from the ISA, such studies report PM<sub>2.5</sub>-induced changes in markers of cardiovascular function and provide strong support for the biological plausibility of the more serious cardiovascular-related outcomes observed in epidemiologic studies (sections 3.2.1 and 3.2.3.1). Unlike most epidemiologic studies, available controlled human exposure studies provide support for effects following single, short-term PM<sub>2.5</sub> exposures to concentrations that typically correspond to the upper end of the PM<sub>2.5</sub> air quality distribution in the U.S. (i.e., “peak” concentrations). In evaluating what such controlled human exposure studies may indicate regarding the primary standards, we consider the effects reported following PM<sub>2.5</sub> exposures, the exposure concentrations/durations reported to cause those effects, and the degree to which air quality analyses indicate that such exposures are likely to occur in areas meeting the current or alternative PM<sub>2.5</sub> standards.<sup>13</sup>

Consideration of the evidence and related air quality analyses, as summarized above, informs our evaluation of the public health protection provided by the combination of the current annual and 24-hour primary PM<sub>2.5</sub> standards, as well as the protection that could be provided by alternative annual and 24-hour standards with revised levels (section 3.4). There are various ways to combine an annual standard (based on arithmetic mean concentrations) and a 24-hour standard (based on 98<sup>th</sup> percentile concentrations), to achieve an appropriate degree of public health protection. The extent to which the standards are interrelated in any given area depends in large part on the relative levels of the standards, the peak-to-mean ratios that characterize air quality patterns in the area, and whether changes in air quality designed to meet a given suite of standards are likely to be of a more regional or more localized nature. In considering the combined effects of the standards, we recognize that changes in PM<sub>2.5</sub> air quality designed to meet an annual standard would likely result not only in lower short- and long-term PM<sub>2.5</sub> concentrations near the middle of the air quality distribution (i.e., around the mean of the distribution), but also in fewer and lower short-term peak PM<sub>2.5</sub> concentrations. Additionally, changes designed to meet a 24-hour standard, with a 98<sup>th</sup> percentile form, would result not only in fewer and lower peak 24-hour PM<sub>2.5</sub> concentrations, but also in lower annual average PM<sub>2.5</sub> concentrations.

However, while either standard could be viewed as providing some measure of protection against both average exposures and peak exposures, the 24-hour and annual standards are not expected to be equally effective at limiting both types of exposures. Specifically, the 24-hour standard (with its 98<sup>th</sup> percentile form) is more directly tied to short-term peak PM<sub>2.5</sub> concentrations than to the more typical concentrations that make up the middle portion of the air

---

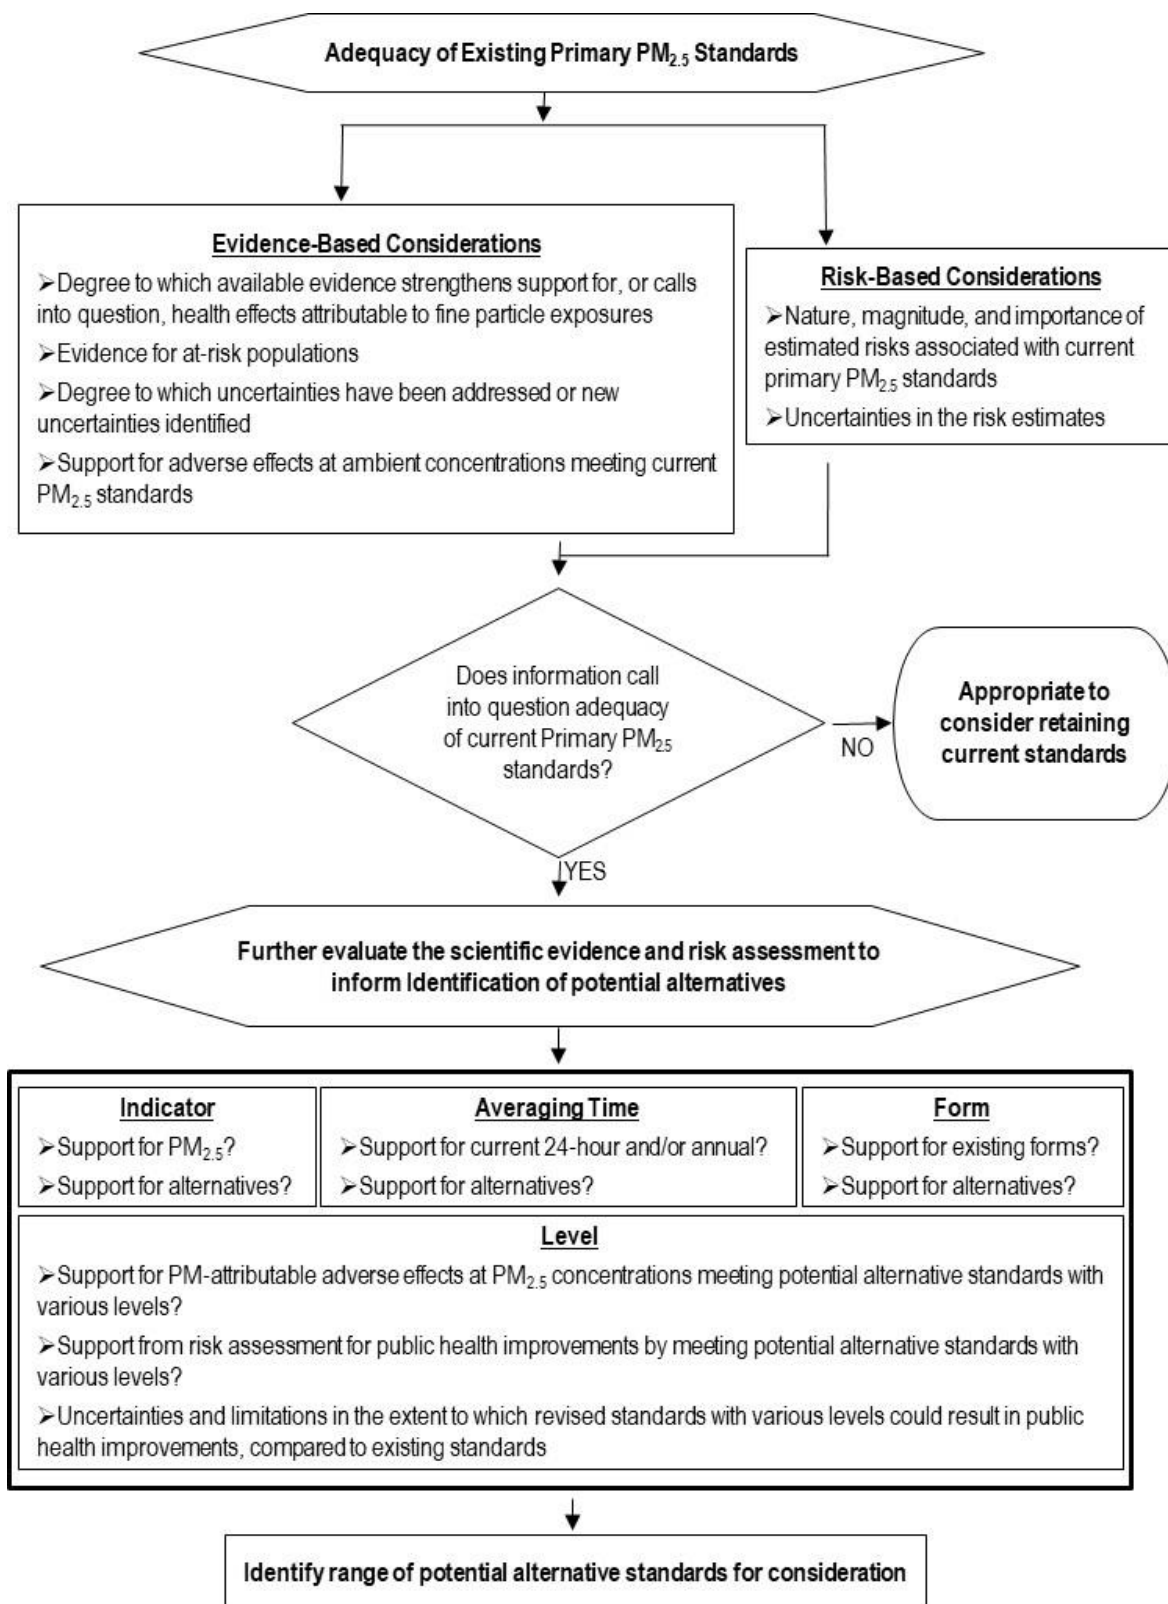

<sup>13</sup> As discussed further in section 3.2.3.1, animal toxicology studies can be similarly evaluated, though there is greater uncertainty in extrapolating the effects seen in animals, and the PM<sub>2.5</sub> exposures and doses that cause those effects, to human populations.

quality distribution, and thus more likely to appropriately limit exposures to peak concentrations. Compared to a standard that is directly tied to the middle of the air quality distribution, the 24-hour standard is less likely to appropriately limit the typical exposures that are most strongly associated with the health effects observed in epidemiologic studies. In contrast, the annual standard, with its form based on the arithmetic mean concentration, is more likely to effectively limit the PM<sub>2.5</sub> concentrations that comprise the middle portion of the air quality distribution, affording protection against the daily and annual PM<sub>2.5</sub> exposures that strongly support associations with the most serious PM<sub>2.5</sub>-related effects in epidemiologic studies (e.g., mortality, hospitalizations).

For these reasons, as in the last review (78 FR 3161-3162, January 15, 2013), we focus on the annual PM<sub>2.5</sub> standard as the principle means of providing public health protection against the bulk of the distribution of short- and long-term PM<sub>2.5</sub> exposures, and thus protecting against the exposures that provide strong support for associations with mortality and morbidity in key epidemiologic studies. We additionally consider the 24-hour standard, with its 98<sup>th</sup> percentile form, as a means of providing supplemental protection against the short-term exposures to peak PM<sub>2.5</sub> concentrations that can occur in areas with strong contributions from local or seasonal sources, even when overall mean PM<sub>2.5</sub> concentrations remain relatively low (section 3.4).

Figure 3-1 summarizes our general approach to informing conclusions on the current primary standards and on potential alternatives. Subsequent sections of this chapter provide additional detail on this general approach.

**Figure 3-1. Overview of general approach for review of primary PM<sub>2.5</sub> standards.**

In adopting the approach outlined above, we recognize that decisions on the primary PM<sub>2.5</sub> standards are largely public health policy judgments to be made by the Administrator. The Administrator's final decisions will draw upon the scientific evidence for PM-related health effects, information from the quantitative assessment of population health risks, information from analyses of air quality, and judgments about how to consider the uncertainties and limitations that are inherent in the evidence and information. To inform the Administrator's public health policy judgments and decisions, the PA considers support for, and the potential implications of, placing more or less weight on various aspects of this evidence, air quality and risk information, and associated uncertainties and limitations.

This approach is consistent with the requirements of the NAAQS provisions of the CAA and with how the EPA and the courts have historically interpreted these CAA provisions. The CAA requires primary standards that, in the judgment of the Administrator, are requisite to protect public health with an adequate margin of safety. In setting primary standards that are "requisite" to protect public health, the EPA's task is to establish standards that are neither more nor less stringent than necessary for this purpose. The requirement that primary standards provide an "adequate margin of safety" is meant to address uncertainties associated with inconclusive scientific and technical information. Thus, as discussed in section 1.1 of this PA, the CAA does not require that primary standards be set at a zero-risk level, but rather at a level that, in the judgment of the Administrator, limits risk sufficiently so as to protect public health with an adequate margin of safety.

## 3.2 EVIDENCE-BASED CONSIDERATIONS

In this section, we draw from the EPA's synthesis and assessment of the scientific evidence presented in the ISA (U.S. EPA, 2019) to consider the following policy-relevant question:

- **To what extent does the currently available scientific evidence, as assessed in the ISA, support or call into question the public health protection afforded by the current suite of PM<sub>2.5</sub> standards?**

The ISA uses a weight-of-evidence framework for characterizing the strength of the available scientific evidence for health effects attributable to PM exposures (U.S. EPA, 2015, Preamble, Section 5). This framework provides the basis for robust, consistent, and transparent evaluation of the scientific evidence, including its uncertainties, and for drawing conclusions on PM-related health effects. As in the last review (U.S. EPA, 2009), the ISA for this review has adopted a five-level hierarchy to classify the overall weight of evidence into one of the following categories: causal relationship; likely to be a causal relationship; suggestive of, but not sufficient to infer, a causal relationship; inadequate to infer a causal relationship; and not likely to be a causal

relationship (U.S. EPA, 2015, Preamble Table II). In using the weight-of-evidence approach to inform judgments about the likelihood that various health effects are caused by PM exposures, evidence is evaluated for major outcome categories or groups of related outcomes (e.g., respiratory effects), integrating evidence from across disciplines, including epidemiologic, controlled human exposure, and animal toxicological studies and evaluating the coherence of evidence across a spectrum of related endpoints (U.S. EPA, 2015, Preamble, Section 5.c.). In this PA, we consider the full body of health evidence, placing the greatest emphasis on the health effects for which the evidence has been judged in the ISA to demonstrate a “causal” or a “likely to be causal” relationship with PM exposures. The ISA defines these causality determinations as follows (U.S. EPA, 2019, p. p-20):

- Causal relationship: the pollutant has been shown to result in health effects at relevant exposures based on studies encompassing multiple lines of evidence and chance, confounding, and other biases can be ruled out with reasonable confidence.
- Likely to be a causal relationship: there are studies in which results are not explained by chance, confounding, or other biases, but uncertainties remain in the health effects evidence overall. For example, the influence of co-occurring pollutants is difficult to address, or evidence across scientific disciplines may be limited or inconsistent.

In the sections below, we consider the nature of the health effects attributable to long- and short-term fine particle exposures (Section 3.2.1), the populations potentially at increased risk for PM-related effects (Section 3.2.2), and the PM<sub>2.5</sub> concentrations at which effects have been shown to occur (Section 3.2.3).

### 3.2.1 Nature of Effects

In considering the available evidence for health effects attributable to PM<sub>2.5</sub> exposures presented in the ISA, this section poses the following policy-relevant questions:

- **To what extent does the currently available scientific evidence strengthen, or otherwise alter, our conclusions from the last review regarding health effects attributable to long- or short-term fine particle exposures? Have previously identified uncertainties been reduced? What important uncertainties remain and have new uncertainties been identified?**

In answering these questions, as noted above, we consider the full body of evidence assessed in the ISA, placing particular emphasis on health outcomes for which the evidence supports either a “causal” or a “likely to be causal” relationship. While the strongest evidence focuses on PM<sub>2.5</sub>, the ISA also assesses the evidence for the ultrafine fraction of PM<sub>2.5</sub> (ultrafine particles or UFP),

generally considered as particulates with a diameter less than or equal to  $0.1\ \mu\text{m}$ <sup>14</sup> (typically based on physical size, thermal diffusivity or electrical mobility) (U.S. EPA, 2019, Preface, p. 11). Table 3-1 lists the health outcomes for which the ISA concludes the evidence supports either a causal, a likely to be causal, or a suggestive relationship (adapted from U.S. EPA, 2019, Table 1-4).

---

<sup>14</sup> Though definitions of UFP vary across the scientific literature and, as discussed in sections 3.2.1.5 and 3.2.1.6, UFP exposures in animal toxicological and controlled human exposure studies typically use a particle concentrator, which can result in exposures to particles  $> 0.1\ \mu\text{m}$  in diameter in some studies of UFP-related health effects.

**Table 3-1. Key causality determinations for PM<sub>2.5</sub> and UFP exposures.**

Health Outcome	Size Fraction	Exposure Duration	2009 PM ISA	2019 PM ISA
Mortality	PM <sub>2.5</sub>	Long-term	Causal	Causal
		Short-term		
Cardiovascular effects	PM <sub>2.5</sub>	Long-term	Causal	Causal
		Short-term		
	UFP	Short-term	Suggestive of, but not sufficient to infer	Suggestive of, but not sufficient to infer
Respiratory effects	PM <sub>2.5</sub>	Long-term	Likely to be causal	Likely to be causal
		Short-term		
	UFP	Short-term	Suggestive of, but not sufficient to infer	Suggestive of, but not sufficient to infer
Cancer	PM <sub>2.5</sub>	Long-term	Suggestive of, but not sufficient to infer	Likely to be causal
Nervous System effects	PM <sub>2.5</sub>	Long-term	---	Likely to be causal
		Short-term	Inadequate	Suggestive of, but not sufficient to infer
	UFP	Long-term	---	Suggestive of, but not sufficient to infer
		Short-term	Inadequate	Suggestive of, but not sufficient to infer
Metabolic effects	PM <sub>2.5</sub>	Long-term	---	Suggestive of, but not sufficient to infer
		Short-term	---	Suggestive of, but not sufficient to infer
Reproduction and Fertility	PM <sub>2.5</sub>	Long-, Short-term	Suggestive of, but not sufficient to infer	Suggestive of, but not sufficient to infer
Pregnancy and Birth Outcomes				

Table 3-1 lists the health outcomes for which the ISA concludes the evidence supports either a causal, a likely to be causal, or a suggestive relationship. For other health outcomes, the ISA concludes the evidence is inadequate to infer a causal relationship (U.S. EPA, 2019, Table 1-4).

The 2009 ISA (U.S. EPA, 2009) made causality determinations for the broad category of “Reproductive and Developmental Effects.” Causality determinations for 2009 represent this broad category and not specifically for “Male and Female Reproduction and Fertility” and “Pregnancy and Birth Outcomes”.

For reproductive and developmental effects, the ISA’s causality determinations reflect the combined evidence for both short- and long-term exposures (U.S. EPA, 2019, Chapter 9).

Sections 3.2.1.1 to 3.2.1.5 summarize the evidence supporting the ISA’s “causal” and “likely to be causal” determinations for PM<sub>2.5</sub> (bold, italics in Table 3-1). Section 3.2.1.6 briefly summarizes the evidence supporting the ISA’s “suggestive” determinations. Each of these sections focuses on addressing the policy-relevant questions posed above. Section 3.2.1.7 summarizes the evidence in preceding sections and revisits the policy-relevant questions posed above.

### **3.2.1.1 Mortality**

#### Long-term PM<sub>2.5</sub> exposures

In the last review, the 2009 PM ISA reported that the evidence was “sufficient to conclude that the relationship between long-term PM<sub>2.5</sub> exposures and mortality is causal” (U.S. EPA, 2009, p. 7-96). The strongest evidence supporting this conclusion was provided by epidemiologic studies, particularly those examining two seminal cohort, the American Cancer Society (ACS) and the Harvard Six Cities cohorts. Analyses of the Harvard Six Cities cohort included demonstrations that reductions in ambient PM<sub>2.5</sub> concentrations are associated with reduced mortality risk (Laden et al., 2006) and with increases in life expectancy (Pope et al., 2009). Further support was provided by other cohort studies conducted in North America and Europe that also reported positive associations between long-term PM<sub>2.5</sub> exposures and risk of mortality (U.S. EPA, 2009).

Recent cohort studies, which have become available since the 2009 ISA, continue to provide consistent evidence of positive associations between long-term PM<sub>2.5</sub> exposures and mortality. These studies add support for associations with total and non-accidental mortality,<sup>15</sup> as well as with specific causes of death, including cardiovascular disease and respiratory disease (U.S. EPA, 2019, section 11.2.2). Many of these recent studies have extended the follow-up periods originally evaluated in the ACS and Harvard Six Cities cohorts and continue to observe positive associations between long-term PM<sub>2.5</sub> exposures and mortality (U.S. EPA, 2019, section 11.2.2.1; Figures 11-18 and 11-19). Adding to recent evaluations of the ACS and Six Cities cohorts, studies conducted in other cohorts also demonstrate consistent, positive associations between long-term PM<sub>2.5</sub> exposure and mortality across various demographic groups (e.g., age, sex, occupation), spatial and temporal extents, exposure assessment metrics, and statistical techniques (U.S. EPA, 2019, sections 11.2.2.1, 11.2.5). This includes some of the largest cohort studies conducted to date, with analyses of the U.S. Medicare cohort that include nearly 61 million enrollees (Di et al., 2017b) and studies that control for a range of individual and

---

<sup>15</sup> The majority of these studies examined non-accidental mortality outcomes, though some Medicare studies lack cause-specific death information and, therefore, examine total mortality.

ecological covariates, such as race, age, socioeconomic status, smoking status, body mass index, and annual weather variables (e.g., temperature, humidity).

A recent series of retrospective studies has additionally tested the hypothesis that past reductions in ambient PM<sub>2.5</sub> concentrations have been associated with increased life expectancy or a decreased mortality rate (U.S. EPA, 2019, section 11.2.2.5). In their original study, Pope et al. (2009) used air quality data in a cross-sectional analysis from 51 metropolitan areas across the U.S., beginning in the 1970s through the early 2000s, to demonstrate that a 10 µg/m<sup>3</sup> decrease in long-term PM<sub>2.5</sub> concentration was associated with a 0.61-year increase in life expectancy. In a subsequent analysis, these authors extended the period of analysis to include 2000 to 2007 (Correia et al., 2013), a time period with lower ambient PM<sub>2.5</sub> concentrations. In this follow-up study, a decrease in long-term PM<sub>2.5</sub> concentration continued to be associated with an increase in life expectancy, though the magnitude of the increase was smaller than during the earlier time period (i.e., a 10 µg/m<sup>3</sup> decrease in long-term PM<sub>2.5</sub> concentration was associated with a 0.35-year increase in life expectancy). Additional studies conducted in the U.S. or Europe similarly report that reductions in ambient PM<sub>2.5</sub> are associated with improvements in longevity (U.S. EPA, 2019, section 11.2.2.5).

The ISA specifically evaluates the degree to which recent studies that examine the relationship between long-term PM<sub>2.5</sub> exposure and mortality have addressed key policy-relevant issues and/or previously identified data gaps in the scientific evidence. For example, based on its assessment of the evidence, the ISA concludes that positive associations between long-term PM<sub>2.5</sub> exposures and mortality are robust across recent analyses using various approaches to estimate PM<sub>2.5</sub> exposures (e.g., based on monitors, modeling, satellites, or hybrid methods that combine information from multiple sources) (U.S. EPA, 2019, section 11.2.5.1). This includes a recent study (Hart et al. (2015) reporting that correction for bias due to exposure measurement error increases the magnitude of the hazard ratios (confidence intervals widen but the association remains statistically significant), suggesting that failure to correct for exposure measurement error could result in attenuation or underestimation of risk estimates. The ISA additionally concludes that positive associations between long-term PM<sub>2.5</sub> exposures and mortality are robust across statistical models that use different approaches to control for confounders or different sets of confounders (U.S. EPA, 2019, sections 11.2.3 and 11.2.5), across diverse geographic regions and populations, and across a range of temporal periods including the periods of declining PM concentrations (U.S. EPA, 2019, sections 11.2.2.5 and 11.2.5.3). Recent evidence further demonstrates that associations with mortality remain robust in copollutants analyses (U.S. EPA, 2019, section 11.2.3), and that associations persist in analyses restricted to long-term exposures below 12 µg/m<sup>3</sup> (Di et al., 2017b) or 10 µg/m<sup>3</sup> (Shi et al., 2016) (i.e., indicating that risks are not disproportionately driven by the upper portions of the air quality distribution).

An emerging group of studies explores the use of causal inference methods to further evaluate the causal nature of relationships between long-term PM<sub>2.5</sub> exposure and mortality (U.S. EPA, 2019, section 11.2.2.4). The goal of these methods is to “estimate the difference (or ratio) in the expected value of [an] outcome in the population under the exposure they received versus what it would have been had they received an alternative exposure” (Schwartz et al., 2015). For example, Wang et al. (2016)) observe a positive and statistically significant relationship between long-term exposure to PM<sub>2.5</sub> and total (nonaccidental) mortality in New Jersey using a difference-in-difference approach to control for geographical differences, long-term temporal trends, and temperature. Additionally, a few recent studies use statistical techniques to reduce uncertainties related to potential confounding in order to further inform conclusions on causality for long-term PM<sub>2.5</sub> exposure and mortality. For example, studies by Greven et al. (2011) and Pun et al. (2017) decompose ambient PM<sub>2.5</sub> into “spatial” and “spatiotemporal” components in order to evaluate the potential for bias due to unmeasured spatial confounding. The results of these analyses suggest the presence of unmeasured confounding for several health outcomes, though they do not indicate the direction or magnitude of the bias that could result.<sup>16 17</sup>

An additional important consideration in characterizing the public health impacts associated with PM<sub>2.5</sub> exposure is whether concentration-response relationships are linear across the range of concentrations or if nonlinear relationships exist along any part of this range. Several recent studies examine this issue, and continue to provide evidence of linear, no-threshold relationships between long-term PM<sub>2.5</sub> exposures and all-cause and cause-specific mortality (U.S. EPA, 2019, section 11.2.4). Though available studies have not systematically evaluated alternatives to a linear fitted model of concentration-response relationships, potential deviations from linearity have been assessed in individual studies using a variety of approaches (U.S. EPA, 2019, Table 11-7). However, interpreting the shapes of these relationships, particularly at PM<sub>2.5</sub> concentrations near the lower end of the air quality distribution, can be complicated by relatively low data density in the lower concentration range, the possible influence of exposure measurement error, and variability among individuals with respect to air pollution health effects. These sources

---

<sup>16</sup> In public comments on the draft PA, the authors of the Pun et al. study further note that “the presence of unmeasured confounding...was expected given that we did not control for several potential confounders that may impact PM<sub>2.5</sub>-mortality associations, such as smoking, socio-economic status (SES), gaseous pollutants, PM<sub>2.5</sub> components, and long-term time trends in PM<sub>2.5</sub>” and that “spatial confounding may bias mortality risks both towards and away from the null” (Docket ID EPA-HQ-OAR-2015-0072-0065; accessible in <https://www.regulations.gov/>)

<sup>17</sup> In its letter on the draft PA, the CASAC cites the study by Eum et al. (2018), which evaluates approaches similar to those in Greven et al. (2011) and Pun et al. (2017). Eum et al. (2018) concludes that associations between 1-year PM<sub>2.5</sub> exposures and mortality “were likely confounded by long-term temporal trends in PM<sub>2.5</sub>” but that controlling for this confounding still resulted in a statistically significant “11.7% increase in all-cause mortality among Medicare beneficiaries for a 10 µg/m<sup>3</sup> increase in PM<sub>2.5</sub>.”

of variability and uncertainty tend to smooth and “linearize” population-level concentration-response functions, and thus could obscure the existence of a threshold or nonlinear relationship (U.S. EPA, 2015, section 6.c).

The biological plausibility of PM<sub>2.5</sub>-attributable mortality is supported by the coherence of effects across scientific disciplines (i.e., animal toxicological, controlled human exposure studies, and epidemiologic), including in recent studies evaluating the morbidity effects that are the largest contributors to total (nonaccidental) mortality. The ISA outlines the available evidence for plausible pathways by which inhalation exposure to PM<sub>2.5</sub> could progress from initial events (e.g., pulmonary inflammation, autonomic nervous system activation) to endpoints relevant to population outcomes, particularly those related to cardiovascular diseases such as ischemic heart disease, stroke and atherosclerosis (U.S. EPA, 2019, section 6.2.1), and to metabolic disease and diabetes (U.S. EPA, 2019, section 7.3.1). The ISA notes “more limited evidence from respiratory morbidity” (U.S. EPA, 2019, p. 11-101) such as exacerbation of COPD (U.S. EPA, 2019, section 5.2.1) to support the biological plausibility of mortality due to long-term PM<sub>2.5</sub> exposures (U.S. EPA, 2019, section 11.2.1).

Taken together, recent studies reaffirm and further strengthen the body of evidence from the 2009 ISA for the relationship between long-term PM<sub>2.5</sub> exposure and mortality. Recent epidemiologic studies consistently report positive associations with mortality across different geographic locations, populations, and analytic approaches. Such studies reduce key uncertainties identified in the last review, including those related to potential copollutant confounding, and provide additional information on the shape of the concentration-response curve. Recent experimental and epidemiologic evidence for cardiovascular effects, and respiratory effects to a more limited degree, supports the plausibility of mortality due to long-term PM<sub>2.5</sub> exposures. The ISA concludes that, “collectively, this body of evidence is sufficient to conclude that a causal relationship exists between long-term PM<sub>2.5</sub> exposure and total mortality” (U.S. EPA, 2019, section 11.2.7; p. 11-102).

#### Short-term PM<sub>2.5</sub> exposures

The 2009 PM ISA concluded that “a causal relationship exists between short-term exposure to PM<sub>2.5</sub> and mortality” (U.S. EPA, 2009). This conclusion was based on the evaluation of both multi- and single-city epidemiologic studies that consistently reported positive associations between short-term PM<sub>2.5</sub> exposure and non-accidental mortality. These associations were strongest, in terms of magnitude and precision, primarily at lags of 0 to 1 days. Examination of the potential confounding effects of gaseous copollutants was limited, though evidence from single-city studies indicated that gaseous copollutants have minimal effect on the PM<sub>2.5</sub>-mortality relationship (i.e., associations remain robust to inclusion of other pollutants in copollutant models). The evaluation of cause-specific mortality found that effect estimates were

larger in magnitude, but also had larger confidence intervals, for respiratory mortality compared to cardiovascular mortality. Although the largest mortality risk estimates were for respiratory mortality, the interpretation of the results was complicated by the limited coherence from studies of respiratory morbidity. However, the evidence from studies of cardiovascular morbidity provided both coherence and biological plausibility for the relationship between short-term PM<sub>2.5</sub> exposure and cardiovascular mortality.

Recent multicity studies evaluated since the 2009 ISA continue to provide evidence of primarily positive associations between daily PM<sub>2.5</sub> exposures and mortality, with percent increases in total mortality ranging from 0.19% (Lippmann et al., 2013) to 2.80% (Kloog et al., 2013)<sup>18</sup> at lags of 0 to 1 days in single-pollutant models. Whereas most studies rely on assigning exposures using data from ambient monitors, associations are also reported in recent studies that employ hybrid modeling approaches using additional PM<sub>2.5</sub> data (i.e., from satellites, land use information, and modeling, in addition to monitors), allowing for the inclusion of more rural locations in analyses (Kloog et al., 2013, Shi et al., 2016, Lee et al., 2015).

Some recent studies have expanded the examination of potential confounders, including long-term temporal trends, weather, and co-occurring pollutants. Mortality associations were found to remain positive, although in some cases were attenuated, when using different approaches to account for temporal trends or weather covariates (U.S. EPA, 2019, section 11.1.5.1). For example, Sacks et al. (2012) examined the influence of model specification using the approaches for confounder adjustment from models employed in several recent multicity studies within the context of a common data set (U.S. EPA, 2019, section 11.1.5.1). These models use different approaches to control for long-term temporal trends and the potential confounding effects of weather. The authors report that associations between daily PM<sub>2.5</sub> and cardiovascular mortality were similar across models, with the percent increase in mortality ranging from 1.5–2.0% (U.S. EPA, 2019, Figure 11-4). Thus, alternative approaches to controlling for long-term temporal trends and for the potential confounding effects of weather may influence the magnitude of the association between PM<sub>2.5</sub> exposures and mortality but have not been found to influence the direction of the observed association (U.S. EPA, 2019, section 11.1.5.1). Taken together, the ISA concludes that recent multicity studies conducted in the U.S., Canada, Europe, and Asia continue to provide consistent evidence of positive associations between short-term PM<sub>2.5</sub> exposures and total mortality across studies that use different approaches to control for the potential confounding effects of weather (e.g., temperature) (U.S. EPA, 2019, section 1.4.1.5.1).

---

<sup>18</sup> As detailed in the Preface to the ISA, risk estimates are for a 10 µg/m<sup>3</sup> increase in 24-hour avg PM<sub>2.5</sub> concentrations, unless otherwise noted (U.S. EPA, 2019).

With regard to copollutants, recent studies provide additional evidence that associations between short-term PM<sub>2.5</sub> exposures and mortality remain positive and relatively unchanged in copollutant models with both gaseous pollutants and PM<sub>10-2.5</sub> (U.S. EPA, 2019, Section 11.1.4). Additionally, the low ( $r < 0.4$ ) to moderate correlations ( $r = 0.4-0.7$ ) between PM<sub>2.5</sub> and gaseous pollutants and PM<sub>10-2.5</sub> increase the confidence in PM<sub>2.5</sub> having an independent effect on mortality (U.S. EPA, 2019, section 11.1.4).

The generally positive associations reported with mortality are supported by a small group of studies employing causal inference or quasi-experimental statistical approaches (U.S. EPA, 2019, section 11.1.2.1). For example, two studies by Schwartz et al. (Schwartz et al., 2015; Schwartz et al., 2017) report associations between PM<sub>2.5</sub> instrumental variables and mortality (U.S. EPA, 2019, Table 11-2), including in an analysis limited to days with 24-hour average PM<sub>2.5</sub> concentrations  $<30 \mu\text{g}/\text{m}^3$  (Schwartz et al., 2017). In addition to the main analyses, these studies conducted Granger-like causality tests as sensitivity analyses to examine whether there was evidence of an association between mortality and PM<sub>2.5</sub> after the day of death, which would support the possibility that unmeasured confounders were not accounted for in the statistical model. Neither study reports evidence of an association with PM<sub>2.5</sub> after death (i.e., they do not indicate unmeasured confounding). A recent quasi-experimental study examines whether a specific regulatory action in Tokyo, Japan (i.e., a diesel emission control ordinance) resulted in a subsequent reduction in daily mortality (Yorifuji et al., 2016). The authors report a reduction in mortality in Tokyo due to the ordinance, compared to Osaka, which did not have a similar diesel emission control ordinance in place.

The positive associations for total mortality reported across the majority of studies evaluated are further supported by analyses reporting generally consistent, positive associations with both cardiovascular and respiratory mortality (U.S. EPA, 2019, section 11.1.3). For both cardiovascular and respiratory mortality, there has been only limited assessment of potential copollutant confounding, though initial evidence indicates that associations remain positive and relatively unchanged in models with gaseous pollutants and PM<sub>10-2.5</sub>. This evidence further supports the copollutant analyses conducted for total mortality. The strong evidence for ischemic events and heart failure, as detailed in the assessment of cardiovascular morbidity (U.S. EPA, 2019, Chapter 6), provides biological plausibility for PM<sub>2.5</sub>-related cardiovascular mortality, which comprises the largest percentage of total mortality (i.e., ~33%) (NHLBI, 2017). Although there is evidence for exacerbations of COPD and asthma, the collective body of respiratory morbidity evidence provides only limited biological plausibility for PM<sub>2.5</sub>-related respiratory mortality (U.S. EPA, 2019, Chapter 5).

In the 2009 ISA, one of the main uncertainties identified was the regional and city-to-city heterogeneity in PM<sub>2.5</sub>-mortality associations. Recent studies examine both city-specific as well

as regional characteristics to identify the underlying contextual factors that could contribute to this heterogeneity (U.S. EPA, 2019, section 11.1.6.3). Analyses focusing on effect modification of the PM<sub>2.5</sub>-mortality relationship by PM<sub>2.5</sub> components, regional patterns in PM<sub>2.5</sub> components and city-specific differences in composition and sources indicate some differences in the PM<sub>2.5</sub> composition and sources across cities and regions, but these differences do not fully explain the observed heterogeneity. Additional studies find that factors related to potential exposure differences, such housing stock and commuting, as well as city-specific factors (e.g., land-use, port volume, and traffic information), may explain some of the observed heterogeneity (U.S. EPA, 2019, section 11.1.6.3). Collectively, recent studies indicate that the heterogeneity in PM<sub>2.5</sub>-mortality risk estimates cannot be attributed to one factor, but instead a combination of factors including, but not limited to, PM composition and sources as well as community characteristics that could influence exposures (U.S. EPA, 2019, section 11.1.12).

A number of recent studies conducted systematic evaluations of the lag structure of associations for the PM<sub>2.5</sub>-mortality relationship by examining either a series of single-day or multiday lags and these studies continue to support an immediate effect (i.e., lag 0 to 1 days) of short-term PM<sub>2.5</sub> exposures on mortality (U.S. EPA, 2019, section 11.1.8.1). Recent studies also conducted analyses comparing the traditional 24-hour average exposure metric with a sub-daily metric (i.e., 1-hour max). These initial studies provide evidence of a similar pattern of associations for both the 24-hour average and 1-hour max metric, with the association larger in magnitude for the 24-hour average metric.

Recent multicity studies indicate that positive and statistically significant associations with mortality persist in analyses restricted to short-term PM<sub>2.5</sub> exposures below 35 µg/m<sup>3</sup> (Lee et al., 2015),<sup>19</sup> below 30 µg/m<sup>3</sup> (Shi et al., 2016), and below 25 µg/m<sup>3</sup> (Di et al., 2017a), indicating that risks associated with short-term PM<sub>2.5</sub> exposures are not disproportionately driven by the peaks of the air quality distribution. Additional studies examine the shape of the concentration-response relationship and whether a threshold exists specifically for PM<sub>2.5</sub> (U.S. EPA, 2019, section 11.1.10). These studies have used various statistical approaches and consistently demonstrate a linear relationship with no evidence of a threshold. Recent analyses provide initial evidence indicating that PM<sub>2.5</sub>-mortality associations persist and may be stronger (i.e., a steeper slope) at lower concentrations (e.g., Di et al., 2017a; Figure 11-12 in U.S. EPA, 2019). However, given the limited data available at the lower end of the distribution of ambient PM<sub>2.5</sub> concentrations, the shape of the concentration-response curve remains uncertain at these low concentrations and, to date, studies have not conducted extensive analyses exploring

---

<sup>19</sup> Lee et al. (2015) also report that positive and statistically significant associations between short-term PM<sub>2.5</sub> exposures and mortality persist in analyses restricted to areas with long-term concentrations below 12 µg/m<sup>3</sup>.

alternatives to linearity when examining the shape of the PM<sub>2.5</sub>-mortality concentration-response relationship.

Overall, recent epidemiologic studies build upon and extend the conclusions of the 2009 ISA for the relationship between short-term PM<sub>2.5</sub> exposures and total mortality. Supporting evidence for PM<sub>2.5</sub>-related cardiovascular morbidity, and more limited evidence from respiratory morbidity, provides biological plausibility for mortality due to short-term PM<sub>2.5</sub> exposures. The primarily positive associations observed across studies conducted in diverse geographic locations is further supported by the results from co-pollutant analyses indicating robust associations, along with evidence from analyses of the concentration-response relationship. The ISA states that, collectively, “this body of evidence is sufficient to conclude that a causal relationship exists between short-term PM<sub>2.5</sub> exposure and total mortality” (U.S. EPA, 2019, pp. 11-58).

### **3.2.1.2 Cardiovascular Effects**

#### Long-term PM<sub>2.5</sub> exposures

The scientific evidence reviewed in the 2009 PM ISA was “sufficient to infer a causal relationship between long-term PM<sub>2.5</sub> exposure and cardiovascular effects” (U.S. EPA, 2009). The strongest line of evidence comprised findings from several large epidemiologic studies of U.S. cohorts that consistently showed positive associations between long-term PM<sub>2.5</sub> exposure and cardiovascular mortality (Pope et al., 2004, Krewski et al., 2009, Miller et al., 2007, Laden et al., 2006). Studies of long-term PM<sub>2.5</sub> exposure and cardiovascular morbidity were limited in number. Biological plausibility and coherence with the epidemiologic findings were provided by studies using genetic mouse models of atherosclerosis demonstrating enhanced atherosclerotic plaque development and inflammation, as well as changes in measures of impaired heart function, following 4- to 6-month exposures to PM<sub>2.5</sub> concentrated ambient particles (CAPs), and by a limited number of studies reporting CAPs-induced effects on coagulation factors, vascular reactivity, and worsening of experimentally induced hypertension in mice (U.S. EPA, 2009).

Consistent with the evidence assessed in the 2009 PM ISA, the 2019 ISA concludes that recent studies, together with the evidence available in previous reviews, support a causal relationship between long-term exposure to PM<sub>2.5</sub> and cardiovascular effects. As discussed above (section 3.2.1.1), results from recent U.S. and Canadian cohort studies consistently report positive associations between long-term PM<sub>2.5</sub> exposure and cardiovascular mortality (U.S. EPA, 2019, Figure 6-19) in evaluations conducted at varying spatial scales and employing a variety of exposure assessment and statistical methods (U.S. EPA, 2019, section 6.2.10). Positive associations between long-term PM<sub>2.5</sub> exposures and cardiovascular mortality are generally robust in copollutant models adjusted for ozone, NO<sub>2</sub>, PM<sub>10-2.5</sub>, or SO<sub>2</sub>. In addition, most of the results from analyses examining the shape of the concentration-response relationship for

cardiovascular mortality support a linear relationship with long-term PM<sub>2.5</sub> exposures and do not identify a threshold below which effects do not occur (U.S. EPA, 2019, section 6.2.16; Table 6-52).<sup>20</sup>

The body of literature examining the relationship between long-term PM<sub>2.5</sub> exposure and cardiovascular morbidity has greatly expanded since the 2009 PM ISA, with positive associations reported in several cohorts (U.S. EPA, 2019, section 6.2). Though results for cardiovascular morbidity are less consistent than those for cardiovascular mortality (U.S. EPA, 2019, section 6.2), recent studies provide some evidence for associations between long-term PM<sub>2.5</sub> exposures and the progression of cardiovascular disease. Positive associations with cardiovascular morbidity (e.g., coronary heart disease, stroke) and atherosclerosis progression are observed in several epidemiologic studies (U.S. EPA, 2019, sections 6.2.2. to 6.2.9). Associations in such studies are supported by toxicological evidence for increased plaque progression in mice following long-term exposure to PM<sub>2.5</sub> collected from multiple locations across the U.S. (U.S. EPA, 2019, section 6.2.4.2). A small number of epidemiologic studies also report positive associations between long-term PM<sub>2.5</sub> exposure and heart failure, changes in blood pressure, and hypertension (U.S. EPA, 2019, sections 6.2.5 and 6.2.7). Associations with heart failure are supported by animal toxicological studies demonstrating decreased cardiac contractility and function, and increased coronary artery wall thickness following long-term PM<sub>2.5</sub> exposure (U.S. EPA, 2019, section 6.2.5.2). Similarly, a limited number of animal toxicological studies demonstrating a relationship between long-term exposure to PM<sub>2.5</sub> and consistent increases in blood pressure in rats and mice are coherent with epidemiologic studies reporting positive associations between long-term exposure to PM<sub>2.5</sub> and hypertension.

Longitudinal epidemiologic analyses also report positive associations with markers of systemic inflammation (U.S. EPA, 2019, section 6.2.11), coagulation (U.S. EPA, 2019, section 6.2.12), and endothelial dysfunction (U.S. EPA, 2019, section 6.2.13). These results are coherent with animal toxicological studies generally reporting increased markers of systemic inflammation, oxidative stress, and endothelial dysfunction (U.S. EPA, 2019, section 6.2.12.2 and 6.2.14).

In summary, the ISA concludes that there is consistent evidence from multiple epidemiologic studies illustrating that long-term exposure to PM<sub>2.5</sub> is associated with mortality from cardiovascular causes. Associations with CHD, stroke and atherosclerosis progression were observed in several additional epidemiologic studies providing coherence with the mortality findings. Results from copollutant models generally support the independence of the PM<sub>2.5</sub> associations. Additional evidence of the independent effect of PM<sub>2.5</sub> on the cardiovascular

---

<sup>20</sup> As noted above for mortality, uncertainty in the shape of the concentration-response relationship increases near the upper and lower ends of the distribution due to limited data.

system is provided by experimental studies in animals, which demonstrate biologically plausible pathways by which long-term inhalation exposure to PM<sub>2.5</sub> could potentially result in outcomes such as CHD, stroke, CHF and cardiovascular mortality. The combination of epidemiologic and experimental evidence results in the ISA conclusion that “a causal relationship exists between long-term exposure to PM<sub>2.5</sub> and cardiovascular effects” (U.S. EPA, 2019, section 6.2.18).

#### Short-term PM<sub>2.5</sub> exposures

The 2009 PM ISA concluded that “a causal relationship exists between short-term exposure to PM<sub>2.5</sub> and cardiovascular effects” (U.S. EPA, 2009). The strongest evidence in the 2009 PM ISA was from epidemiologic studies of ED visits and hospital admissions for IHD and HF, with supporting evidence from epidemiologic studies of cardiovascular mortality (U.S. EPA, 2009). Animal toxicological studies provided coherence and biological plausibility for the positive associations reported with myocardial ischemia ED visit and hospital admissions. These included studies reporting reduced myocardial blood flow during ischemia and studies indicating altered vascular reactivity. In addition, effects of PM<sub>2.5</sub> exposure on a potential indicator of ischemia (i.e., ST segment depression on an electrocardiogram) were reported in both animal toxicological and epidemiologic panel studies.<sup>21</sup> Key uncertainties from the last review resulted from inconsistent results across disciplines with respect to the relationship between short-term exposure to PM<sub>2.5</sub> and changes in blood pressure, blood coagulation markers, and markers of systemic inflammation. In addition, while the 2009 PM ISA identified a growing body of evidence from controlled human exposure and animal toxicological studies, uncertainties remained with respect to biological plausibility.

A large body of recent evidence confirms and extends the evidence from the 2009 ISA indicating that there is a causal relationship between short-term PM<sub>2.5</sub> exposure and cardiovascular effects. This includes generally positive associations observed in multicity epidemiologic studies of emergency department visits and hospital admissions for ischemic heart disease (IHD), heart failure (HF), and combined cardiovascular-related endpoints. In particular, nationwide studies of older adults (65 years and older) using Medicare records report positive associations between PM<sub>2.5</sub> exposures and hospital admissions for HF (U.S. EPA, 2019, section 6.1.3.1). Additional multicity studies conducted in the northeast U.S. report positive associations between short-term PM<sub>2.5</sub> exposures and emergency department visits or hospital admissions for IHD (U.S. EPA, 2019, section 6.1.2.1) while studies conducted in the U.S. and Canada reported positive associations between short-term PM<sub>2.5</sub> exposures and emergency department visits for HF. Epidemiologic studies conducted in single cities contribute some

---

<sup>21</sup> Some animal studies included in the 2009 PM ISA examined exposures to mixtures, such as motor vehicle exhaust or woodsmoke. In these studies, it was unclear if the resulting cardiovascular effects could be attributed specifically to the particulate components of the mixture.

support, though associations reported in single-city studies are less consistently positive than in multicity studies, and include a number of studies reporting null associations (U.S. EPA, 2019, sections 6.1.2 and 6.1.3). When considered as a whole; however, the recent body of IHD and HF epidemiologic evidence supports the evidence from previous ISAs reporting mainly positive associations between short-term PM<sub>2.5</sub> concentrations and emergency department visits and hospital admissions.

In addition, a number of more recent controlled human exposure, animal toxicological, and epidemiologic panel studies provide evidence that PM<sub>2.5</sub> exposure could plausibly result in IHD or HF through pathways that include endothelial dysfunction, arterial thrombosis, and arrhythmia (U.S. EPA, 2019, section 6.1.1). The most consistent evidence from recent controlled human exposure studies is for endothelial dysfunction, as measured by changes in brachial artery diameter or flow mediated dilation. All but one of the available controlled human exposure studies examining the potential for endothelial dysfunction report an effect of PM<sub>2.5</sub> exposure on measures of blood flow (U.S. EPA, 2019, section 6.1.13.2). These studies report variable results regarding the timing of the effect and the mechanism by which reduced blood flow occurs (i.e., availability vs sensitivity to nitric oxide). Some controlled human exposure studies using CAPs report evidence for small increases in blood pressure (U.S. EPA, 2019, section 6.1.6.3). In addition, although not entirely consistent, there is also some evidence across controlled human exposure studies for conduction abnormalities/arrhythmia (U.S. EPA, 2019, section 6.1.4.3), changes in heart rate variability (HRV) (U.S. EPA, 2019, section 6.1.10.2), changes in hemostasis that could promote clot formation (U.S. EPA, 2019, section 6.1.12.2), and increases in inflammatory cells and markers (U.S. EPA, 2019, section 6.1.11.2). Thus, when taken as a whole, controlled human exposure studies are coherent with epidemiologic studies in that they demonstrate short-term exposures to PM<sub>2.5</sub> may result in the types of cardiovascular endpoints that could lead to emergency department visits and hospital admissions in some people.

Animal toxicological studies published since the 2009 ISA also support a relationship between short-term PM<sub>2.5</sub> exposure and cardiovascular effects. A recent study demonstrating decreased cardiac contractility and left ventricular pressure in mice is coherent with the results of epidemiologic studies reporting associations between short-term PM<sub>2.5</sub> exposure and heart failure (U.S. EPA, 2019, section 6.1.3.3). In addition, and as with controlled human exposure studies, there is generally consistent evidence in animal toxicological studies for indicators of endothelial dysfunction (U.S. EPA, 2019, section 6.1.13.3). Studies in animals also provide evidence for changes in a number of other cardiovascular endpoints following short-term PM<sub>2.5</sub> exposure. Although not entirely consistent, these studies provide some evidence of conduction abnormalities and arrhythmia (U.S. EPA, 2019, section 6.1.4.4), changes in HRV (U.S. EPA,

2019, section 6.1.10.3), changes in blood pressure (U.S. EPA, 2019, section 6.1.6.4), and evidence for systemic inflammation and oxidative stress (U.S. EPA, 2019, section 6.1.11.3).

In summary, recent evidence further supports and extends the conclusions of the evidence base reported in the 2009 ISA. In support of epidemiologic studies reporting robust associations in copollutant models, direct evidence for an independent effect of PM<sub>2.5</sub> on cardiovascular effects can be found in a number of controlled human exposure and animal toxicological studies. Coherent with these results are epidemiologic panel studies reporting that PM<sub>2.5</sub> exposure is associated with some of the same cardiovascular endpoints reported in experimental studies. For these effects, there are inconsistencies in results across some animal toxicological, controlled human exposure, and epidemiologic panel studies, though this may be due to substantial differences in study design and/or study populations. Overall, the results from epidemiologic panel, controlled human exposure, and animal toxicological studies, in particular those related to endothelial dysfunction, impaired cardiac function, ST segment depression, thrombosis, conduction abnormalities, and changes in blood pressure provide coherence and biological plausibility for the consistent results from epidemiologic studies observing positive associations between short-term PM<sub>2.5</sub> concentrations and IHD and HF, and ultimately cardiovascular mortality. The ISA concludes that, overall, “there continues to be sufficient evidence to conclude that a causal relationship exists between short-term PM<sub>2.5</sub> exposure and cardiovascular effects” (U.S. EPA, 2019, p. 6-138).

### **3.2.1.3 Respiratory Effects**

#### Long-term PM<sub>2.5</sub> exposures

The 2009 PM ISA concluded that “a causal relationship is likely to exist between long-term PM<sub>2.5</sub> exposure and respiratory effects” (U.S. EPA, 2009). This conclusion was based mainly on epidemiologic evidence demonstrating associations between long-term PM<sub>2.5</sub> exposure and changes in lung function or lung function growth in children. Biological plausibility was provided by a single animal toxicological study examining pre- and post-natal exposure to PM<sub>2.5</sub> CAPs, which found impaired lung development. Epidemiologic evidence for associations between long-term PM<sub>2.5</sub> exposure and other respiratory outcomes, such as the development of asthma, allergic disease, and COPD; respiratory infection; and the severity of disease was limited, both in the number of studies available and the consistency of the results. Experimental evidence for other outcomes was also limited, with one animal toxicological study reporting that long-term exposure to PM<sub>2.5</sub> CAPs results in morphological changes in nasal airways of healthy animals. Other animal studies examined exposure to mixtures, such as motor vehicle exhaust and woodsmoke, and effects were not attributed specifically to the particulate components of the mixture.

Recent cohort studies provide additional support for the relationship between long-term PM<sub>2.5</sub> exposure and decrements in lung function growth (as a measure of lung development), indicating a robust and consistent association across study locations, exposure assessment methods, and time periods (U.S. EPA, 2019, section 5.2.13). This relationship is further supported by a recent retrospective study that reports an association between declining PM<sub>2.5</sub> concentrations and improvements in lung function growth in children (U.S. EPA, 2019, section 5.2.11). Epidemiologic studies also examine asthma development in children (U.S. EPA, 2019, section 5.2.3), with recent prospective cohort studies reporting generally positive associations, though several are imprecise (i.e., they report wide confidence intervals). Supporting evidence is provided by studies reporting associations with asthma prevalence in children, with childhood wheeze, and with exhaled nitric oxide, a marker of pulmonary inflammation (U.S. EPA, 2019, section 5.2.13). A recent animal toxicological study showing the development of an allergic phenotype and an increase in a marker of airway responsiveness provides biological plausibility for allergic asthma (U.S. EPA, 2019, section 5.2.13). Other epidemiologic studies report a PM<sub>2.5</sub>-related acceleration of lung function decline in adults, while improvement in lung function was observed with declining PM<sub>2.5</sub> concentrations (U.S. EPA, 2019, section 5.2.11). A recent longitudinal study found declining PM<sub>2.5</sub> concentrations are also associated with an improvement in chronic bronchitis symptoms in children, strengthening evidence reported in the 2009 ISA for a relationship between increased chronic bronchitis symptoms and long-term PM<sub>2.5</sub> exposure (U.S. EPA, 2019, section 5.2.11). A common uncertainty across the epidemiologic evidence is the lack of examination of copollutants to assess the potential for confounding. While there is some evidence that associations remain robust in models with gaseous pollutants, a number of these studies examining copollutant confounding were conducted in Asia, and thus have limited generalizability due to high annual pollutant concentrations.

When taken together, the ISA concludes that the “epidemiologic evidence strongly supports a relationship with decrements in lung function growth in children” and “with asthma development in children, with increased bronchitic symptoms in children with asthma, with an acceleration of lung function decline in adults, and with respiratory mortality and cause-specific respiratory mortality for COPD and respiratory infection” (U.S. EPA, 2019, p. 1-34). In support of the biological plausibility of such associations reported in epidemiologic studies of respiratory health effects, animal toxicological studies continue to provide direct evidence that long-term exposure to PM<sub>2.5</sub> results in a variety of respiratory effects. Recent animal studies show pulmonary oxidative stress, inflammation, and morphologic changes in the upper (nasal) and lower airways. Other results show that changes are consistent with the development of allergy and asthma, and with impaired lung development. Overall, the ISA concludes that “the collective

evidence is sufficient to conclude that a causal relationship is likely to exist between long-term PM<sub>2.5</sub> exposure and respiratory effects” (U.S. EPA, 2019, section 5.2.13).

#### Short-term PM<sub>2.5</sub> exposures

The 2009 PM ISA (U.S. EPA, 2009) concluded that a “causal relationship is likely to exist” between short-term PM<sub>2.5</sub> exposure and respiratory effects. This conclusion was based mainly on the epidemiologic evidence demonstrating positive associations with various respiratory effects. Specifically, the 2009 ISA described epidemiologic evidence as consistently showing PM<sub>2.5</sub>-associated increases in hospital admissions and emergency department visits for chronic obstructive pulmonary disease (COPD) and respiratory infection among adults or people of all ages, as well as increases in respiratory mortality. These results were supported by studies reporting associations with increased respiratory symptoms and decreases in lung function in children with asthma, though the epidemiologic evidence was inconsistent for hospital admissions or emergency department visits for asthma. Studies examining copollutant models showed that PM<sub>2.5</sub> associations with respiratory effects were robust to inclusion of CO or SO<sub>2</sub> in the model, but often were attenuated (though still positive) with inclusion of O<sub>3</sub> or NO<sub>2</sub>. In addition to the copollutant models, evidence supporting an independent effect of PM<sub>2.5</sub> exposure on the respiratory system was provided by animal toxicological studies of PM<sub>2.5</sub> CAPs demonstrating changes in some pulmonary function parameters, as well as inflammation, oxidative stress, injury, enhanced allergic responses, and reduced host defenses. Many of these effects have been implicated in the pathophysiology for asthma exacerbation, COPD exacerbation, or respiratory infection. In the few controlled human exposure studies conducted in individuals with asthma or COPD, PM<sub>2.5</sub> exposure mostly had no effect on respiratory symptoms, lung function, or pulmonary inflammation. Available studies in healthy people also did not clearly demonstrate respiratory effects following short-term PM<sub>2.5</sub> exposures.

Recent epidemiologic studies provide evidence for a relationship between short-term PM<sub>2.5</sub> exposure and several respiratory-related endpoints, including asthma exacerbation (U.S. EPA, 2019, section 5.1.2.1), COPD exacerbation (U.S. EPA, 2019, section 5.1.4.1), and combined respiratory-related diseases (U.S. EPA, 2019, section 5.1.6), particularly from studies examining emergency department visits and hospital admissions. The generally positive associations between short-term PM<sub>2.5</sub> exposure and asthma and COPD emergency department visits and hospital admissions are supported by epidemiologic studies demonstrating associations with other respiratory-related effects such as symptoms and medication use that are indicative of asthma and COPD exacerbations (U.S. EPA, 2019, sections 5.1.2.2 and 5.4.1.2). The collective body of epidemiologic evidence for asthma exacerbation is more consistent in children than in adults. Additionally, epidemiologic studies examining the relationship between short-term PM<sub>2.5</sub>

exposure and respiratory mortality provide evidence of consistent positive associations, demonstrating a continuum of effects (U.S. EPA, 2019, section 5.1.9).

Building off the studies evaluated in the 2009 ISA, recent epidemiologic studies expand the assessment of potential copollutant confounding. There is some evidence that PM<sub>2.5</sub> associations with asthma exacerbation, combined respiratory-related diseases, and respiratory mortality remain relatively unchanged in copollutant models with gaseous pollutants (i.e., O<sub>3</sub>, NO<sub>2</sub>, SO<sub>2</sub>, with more limited evidence for CO) and other particle sizes (i.e., PM<sub>10-2.5</sub>) (U.S. EPA, 2019, section 5.1.10.1).

The uncertainty related to whether there is an independent effect of PM<sub>2.5</sub> on respiratory health is also partially addressed by findings from animal toxicological studies. Specifically, short-term exposure to PM<sub>2.5</sub> enhanced asthma-related responses in an animal model of allergic airways disease and enhanced lung injury and inflammation in an animal model of COPD (U.S. EPA, 2019, sections 5.1.2.4.4 and 5.1.4.4.3). The experimental evidence provides biological plausibility for some respiratory-related endpoints, including limited evidence of altered host defense and greater susceptibility to bacterial infection as well as consistent evidence of respiratory irritant effects. Animal toxicological evidence for other respiratory effects is inconsistent.

The ISA concludes that “[t]he strongest evidence of an effect of short-term PM<sub>2.5</sub> exposure on respiratory effects is provided by epidemiologic studies of asthma and COPD exacerbation. While animal toxicological studies provide biological plausibility for these findings, some uncertainty remains with respect to the independence of PM<sub>2.5</sub> effects” (U.S. EPA, 2019, p. 5-155). When taken together, the ISA concludes that this evidence “is sufficient to conclude that a causal relationship is likely to exist between short-term PM<sub>2.5</sub> exposure and respiratory effects” (U.S. EPA, 2019, p. 5-155).

#### **3.2.1.4 Cancer – Long-term PM<sub>2.5</sub> Exposures**

The 2009 ISA concluded that the overall body of evidence was “suggestive of a causal relationship between relevant PM<sub>2.5</sub> exposures and cancer” (U.S. EPA, 2009). This conclusion was based primarily on positive associations observed in a limited number of epidemiologic studies of lung cancer mortality. The few epidemiologic studies that had evaluated PM<sub>2.5</sub> exposure and lung cancer incidence or cancers of other organs and systems generally did not show evidence of an association. Toxicological studies did not focus on exposures to specific PM size fractions, but rather investigated the effects of exposures to total ambient PM, or other source-based PM such as wood smoke. Collectively, results of in vitro studies were consistent with the larger body of evidence demonstrating that ambient PM and PM from specific combustion sources are mutagenic and genotoxic. However, animal inhalation studies found

little evidence of tumor formation in response to chronic exposures. A small number of studies provided preliminary evidence that PM exposure can lead to changes in methylation of DNA, which may contribute to biological events related to cancer.

Since the 2009 ISA, additional cohort studies provide evidence that long-term PM<sub>2.5</sub> exposure is positively associated with lung cancer mortality and with lung cancer incidence, and provide initial evidence for an association with reduced cancer survival (U.S. EPA, 2019, section 10.2.5). Reanalyses of the ACS cohort using different years of PM<sub>2.5</sub> data and follow-up, along with various exposure assignment approaches, provide consistent evidence of positive associations between long-term PM<sub>2.5</sub> exposure and lung cancer mortality (U.S. EPA, 2019, Figure 10-3). Additional support for positive associations with lung cancer mortality is provided by recent epidemiologic studies using individual-level data to control for smoking status, by studies of people who have never smoked (though such studies generally report wide confidence intervals due to the small number of lung cancer mortality cases within this population), and in analyses of cohorts that relied upon proxy measures to account for smoking status (U.S. EPA, 2019, section 10.2.5.1.1). Although studies that have evaluated lung cancer incidence, including studies of people who have never smoked, are limited in number, recent studies generally report positive associations with long-term PM<sub>2.5</sub> exposures (U.S. EPA, 2019, section 10.2.5.1.2). A subset of the studies focusing on lung cancer incidence also examined histological subtype, providing some evidence of positive associations for adenocarcinomas, the predominate subtype of lung cancer observed in people who have never smoked (U.S. EPA, 2019, section 10.2.5.1.2). Associations between long-term PM<sub>2.5</sub> exposure and lung cancer incidence were found to remain relatively unchanged, though in some cases confidence intervals widened, in analyses that attempted to reduce exposure measurement error by accounting for length of time at residential address or by examining different exposure assignment approaches (U.S. EPA, 2019, section 10.2.5.1.2).

The ISA evaluates the degree to which recent epidemiologic studies have addressed the potential for confounding by copollutants and the shape of the concentration-response relationship. To date, relatively few studies have evaluated the potential for copollutant confounding of the relationship between long-term PM<sub>2.5</sub> exposure and lung cancer mortality or incidence. The small number of such studies have generally focused on O<sub>3</sub> and report that PM<sub>2.5</sub> associations remain relatively unchanged in copollutant models (U.S. EPA, 2019, section 10.2.5.1.3). However, available studies have not systematically evaluated the potential for copollutant confounding by other gaseous pollutants or by other particle size fractions (U.S. EPA, 2019, section 10.2.5.1.3). Compared to total (non-accidental) mortality (see section 3.2.1.1), fewer studies have examined the shape of the concentration-response curve for cause-specific mortality outcomes, including lung cancer. Several studies have reported no

evidence of deviations from linearity in the shape of the concentration-response relationship (Lepeule et al., 2012; Raaschou-Nielsen et al., 2013; Puett et al., 2014), though authors provided only limited discussions of results (U.S. EPA, 2019, section 10.2.5.1.4).

In support of the biological plausibility of an independent effect of PM<sub>2.5</sub> on cancer, the ISA notes evidence from recent experimental and epidemiologic studies demonstrating that PM<sub>2.5</sub> exposure can lead to a range of effects indicative of mutagenicity, genotoxicity, and carcinogenicity, as well as epigenetic effects (U.S. EPA, 2019, section 10.2.7). For example, both in vitro and in vivo toxicological studies have shown that PM<sub>2.5</sub> exposure can result in DNA damage (U.S. EPA, 2019, section 10.2.2). Although such effects do not necessarily equate to carcinogenicity, the evidence that PM exposure can damage DNA, and elicit mutations, provides support for the plausibility of epidemiologic associations with lung cancer mortality and incidence. Additional supporting studies indicate the occurrence of micronuclei formation and chromosomal abnormalities (U.S. EPA, 2019, section 10.2.2.3), and differential expression of genes that may be relevant to cancer pathogenesis, following PM exposures. Experimental and epidemiologic studies that examine epigenetic effects indicate changes in DNA methylation, providing some support for PM<sub>2.5</sub> exposure contributing to genomic instability (U.S. EPA, 2019, section 10.2.3).

Epidemiologic evidence for associations between PM<sub>2.5</sub> and lung cancer mortality and incidence, together with evidence supporting the biological plausibility of such associations, contributes to the ISA's conclusion that the evidence "is sufficient to conclude that a causal relationship is likely to exist between long-term PM<sub>2.5</sub> exposure and cancer" (U.S. EPA, 2019, section 10.2.7).

### **3.2.1.5 Nervous System Effects**

#### **Long-term PM<sub>2.5</sub> exposures**

Reflecting the very limited evidence available in the last review, the 2009 ISA did not make a causality determination for long-term PM<sub>2.5</sub> exposures and nervous system effects (U.S. EPA, 2009). Since the last review, this body of evidence has grown substantially (U.S. EPA, 2019, section 8.2). Recent animal toxicology studies report that long-term PM<sub>2.5</sub> exposures can lead to morphologic changes in the hippocampus and to impaired learning and memory. This evidence is consistent with epidemiologic studies reporting that long-term PM<sub>2.5</sub> exposure is associated with reduced cognitive function (U.S. EPA, 2019, section 8.2.5). Further, while the evidence is limited, the presence of early markers of Alzheimer's disease pathology has been demonstrated in rodents following long-term exposure to PM<sub>2.5</sub> CAPs. These findings support reported associations with neurodegenerative changes in the brain (i.e., decreased brain volume), all-cause dementia, or hospitalization for Alzheimer's disease in a small number of

epidemiologic studies (U.S. EPA, 2019, section 8.2.6). Additionally, loss of dopaminergic neurons in the substantia nigra, a hallmark of Parkinson disease, has been reported in mice (U.S. EPA, 2019, section 8.2.4), though epidemiologic studies provide only limited support for associations with Parkinson's disease (U.S. EPA, 2019, section 8.2.6). Overall, the lack of consideration of copollutant confounding introduces some uncertainty in the interpretation of epidemiologic studies of nervous system effects, but this uncertainty is partly addressed by the evidence for an independent effect of PM<sub>2.5</sub> exposures provided by experimental animal studies.

In addition to the findings described above, which are most relevant to older adults, several recent studies of neurodevelopmental effects in children have also been conducted. Positive associations between long-term exposure to PM<sub>2.5</sub> during the prenatal period and autism spectrum disorder (ASD) are observed in multiple epidemiologic studies (U.S. EPA, 2019, section 8.2.7.2), while studies of cognitive function provide little support for an association (U.S. EPA, 2019, section 8.2.5.2). Interpretation of these epidemiologic studies is limited due to the small number of studies, their lack of control for potential confounding by copollutants, and uncertainty regarding the critical exposure windows. Biological plausibility is provided for the ASD findings by a study in mice that found inflammatory and morphologic changes in the corpus collosum and hippocampus, as well as ventriculomegaly (i.e., enlarged lateral ventricles) in young mice following prenatal exposure to PM<sub>2.5</sub> CAPs.

Taken together, the ISA concludes that recent studies indicate long-term PM<sub>2.5</sub> exposures can lead to effects on the brain associated with neurodegeneration (i.e., neuroinflammation and reductions in brain volume), as well as cognitive effects in older adults (U.S. EPA, 2019, Table 1-2). Animal toxicology studies provide evidence for a range of nervous system effects in adult animals, including neuroinflammation and oxidative stress, neurodegeneration, and cognitive effects, and effects on neurodevelopment in young animals. The epidemiologic evidence is more limited but studies generally support associations between long-term PM<sub>2.5</sub> exposure and changes in brain morphology, cognitive decrements and dementia. There is also initial, and limited, evidence for neurodevelopmental effects, particularly ASD. The consistency and coherence of the evidence supports the ISA's conclusion that "the collective evidence is sufficient to conclude that a causal relationship is likely to exist between long-term PM<sub>2.5</sub> exposure and nervous system effects" (U.S. EPA, 2019, section 8.2.9).

#### **3.2.1.6 Other Effects**

Compared to the health outcomes discussed above, the ISA concludes that there is greater uncertainty in the evidence linking PM<sub>2.5</sub>, or UFP, exposures with other health outcomes, reflected in conclusions that the evidence is "suggestive of, but not sufficient to infer, a causal relationship." The sections below summarize the daft ISA conclusions for these "suggestive"

outcomes for long-term (Section 3.2.1.6.1) and short-term (Section 3.2.1.6.2) PM<sub>2.5</sub> and UFP exposures.

#### **3.2.1.6.1 Long-term Exposures**

As indicated in Table 3-1 above, the ISA concludes that the evidence is “suggestive of, but not sufficient to infer, a causal relationship” between long-term PM<sub>2.5</sub> exposures and metabolic effects and reproductive and developmental effects (reproduction and fertility; pregnancy and birth outcomes). These conclusions reflect evidence that is “generally supportive but not entirely consistent or is limited overall” where “[c]hance, confounding, and other biases cannot be ruled out” (U.S. EPA, 2019, Preface, p. P-20). The basis for these causality determinations is summarized briefly below.

##### *PM<sub>2.5</sub> – Metabolic effects*

There were no causality determinations for long-term PM<sub>2.5</sub> exposure and metabolic effects in the 2009 ISA (U.S. EPA, 2009). However, the literature pertaining to the effect of long-term exposure to PM<sub>2.5</sub> and metabolic effects has expanded substantially since the 2009 ISA, and consists of both epidemiologic and experimental evidence (U.S. EPA, 2019, section 7.2). Epidemiologic studies report positive associations between long-term PM<sub>2.5</sub> exposure and diabetes-related mortality. In addition, although results were not consistent across cohorts, there is some evidence from epidemiologic studies for positive associations with incident diabetes, metabolic syndrome, and alterations in glucose and insulin homeostasis. Consideration of copollutant confounding was limited. In animal toxicologic studies, there is some support for a relationship between long-term PM<sub>2.5</sub> exposure and metabolic effects from experimental studies demonstrating increased blood glucose, insulin resistance, and inflammation and visceral adiposity but the experimental evidence was not entirely consistent. Based on this evidence, the ISA concludes that, “[o]verall, the collective evidence is suggestive of, but is not sufficient to infer, a causal relationship between long-term PM<sub>2.5</sub> exposure and metabolic effects” (U.S. EPA, 2019, p. 7-52).

##### *PM<sub>2.5</sub> – Reproductive and developmental effects*

The 2009 ISA determined that the evidence was “suggestive of a causal relationship” for the association between long-term PM<sub>2.5</sub> exposure and reproductive and developmental outcomes. The body of literature characterizing these relationships has grown since the 2009 ISA, with much of the evidence focusing on reproduction and fertility or pregnancy and birth outcomes, though important uncertainties persist (U.S. EPA, 2019, sections 9.1.1, 9.1.2, 9.1.5).

Effects of PM<sub>2.5</sub> exposure on sperm have been studied in both epidemiology and toxicology studies and shows the strongest evidence in epidemiologic studies for impaired sperm motility and in animal toxicological studies for impaired spermiation. Epidemiologic evidence on

sperm morphology have reported inconsistent results. Evidence for effects of PM<sub>2.5</sub> exposure on female reproduction also comes from both epidemiology and toxicology studies. In the epidemiologic literature, results on human fertility and fecundity is limited, but the evidence on in vitro fertilization indicates a modest association of PM<sub>2.5</sub> exposures with decreased odds of becoming pregnant. Studies in rodents have shown ovulation and estrus are affected by PM<sub>2.5</sub> exposure. Biological plausibility for outcomes related to male and female fertility and reproduction comes from laboratory animal studies demonstrating genetic and epigenetic changes in germ cells with PM<sub>2.5</sub> exposure. The ISA concludes that, “[c]ollectively, the evidence is suggestive of, but not sufficient to infer, a causal relationship between PM<sub>2.5</sub> exposure and male and female reproduction and fertility” (U.S. EPA, 2019, p. 9-43).

With regard to pregnancy and birth outcomes, while the collective evidence for many of the outcomes examined is not consistent, there are some animal toxicology and epidemiologic studies that indicate an association between PM<sub>2.5</sub> exposures and reduced fetal growth, low birth weight and preterm birth. Most of the epidemiologic studies do not control for co-pollutant confounding and do not identify a specific sensitive window of exposure, but results from animal toxicologic studies provide biological plausibility for these outcomes, as well as support for multiple sensitive windows for PM<sub>2.5</sub> exposure-associated outcomes. There is also epidemiologic evidence for congenital heart defects of different types, as well as biological plausibility to support this outcome from the animal toxicology literature. However, evidence for a relationship between PM<sub>2.5</sub> exposure and various pregnancy-related pathologies, including gestational hypertension, pre-eclampsia and gestational diabetes is inconsistent. Biological plausibility for effects of PM<sub>2.5</sub> exposure and various pregnancy and birth outcomes is provided by studies showing that PM<sub>2.5</sub> exposure in laboratory rodents resulted in impaired implantation and vascular endothelial dysfunction. Coherence with toxicological studies is provided by epidemiologic studies in humans reporting associations with epigenetic changes to the placenta and impaired fetal thyroid function. When taken together, the ISA concludes that the available evidence, including uncertainties that evidence, is “suggestive of, but not sufficient to infer, a causal relationship between exposure to PM<sub>2.5</sub> and pregnancy and birth outcomes” (U.S. EPA, 2019, p. 9-44).

#### *UFP – Nervous System Effects*

The 2009 ISA reported limited animal toxicological evidence of a relationship between long-term exposure to UFP and nervous system effects, with no supporting epidemiologic studies. Recent animal toxicological studies substantially add to this evidence base. Multiple toxicological studies of long-term UFP exposure conducted in adult mice provide consistent evidence of brain inflammation and oxidative stress in the whole brain, hippocampus, and cerebral cortex (U.S. EPA, 2019, section 8.6.3). Studies also found morphologic changes,

specifically neurodegeneration in specific regions of the hippocampus and pathologic changes characteristic of Alzheimer's disease, and initial evidence of behavioral effects in adult mice (U.S. EPA, 2019, sections 8.6.4 and 8.6.5). Toxicological studies examining pre- and post-natal UFP exposures provide extensive evidence for behavioral effects, altered neurotransmitters, neuroinflammation, and morphologic changes (U.S. EPA, 2019, section 8.6.6.2). Persistent ventriculomegaly was observed in male, but not female, mice exposed postnatally to UFP (U.S. EPA, 2019, section 8.6.6). Epidemiologic evidence is limited to a single study of school children that provides support for the experimental results. This study, which did not consider copollutant confounding, reports an association between long-term exposure to UFP, which was measured at the school, and decrements on tests of attention and memory. Uncertainty results from the lack of information on the spatial and temporal variability of UFP exposures on long-term UFP exposures at the population level. Based primarily on the animal toxicological evidence of neurotoxicity and altered neurodevelopment, the ISA concludes that the evidence is “suggestive of, but not sufficient to infer, a causal relationship” between long-term UFP exposure and nervous system effects (U.S. EPA, 2019, section 8.6.7).

#### **3.2.1.6.2 Short-term Exposures**

As indicated in Table 3-1 above, the ISA concludes that the evidence is “suggestive of, but not sufficient to infer, a causal relationship” between short-term PM<sub>2.5</sub> exposures and metabolic effects and nervous system effects. Additionally, the ISA concludes that the evidence is “suggestive” for short-term UFP exposures and cardiovascular effects, respiratory effects, and nervous system effects. As for the outcomes related to long-term exposures, discussed above, these conclusions reflect evidence that is “generally supportive but not entirely consistent or is limited overall” where “[c]hance, confounding, and other biases cannot be ruled out” (U.S. EPA, 2019, Preface, p.P-20). The basis for these causality determinations is summarized briefly below.

##### *PM<sub>2.5</sub> – Metabolic effects*

There were no studies of the effect of short-term PM<sub>2.5</sub> exposure and metabolic effects reviewed in the 2009 ISA (U.S. EPA, 2009). New evidence for a relationship between short-term PM<sub>2.5</sub> exposure and metabolic effects is based on a small number of epidemiologic and animal toxicological studies reporting effects on glucose and insulin homeostasis and other indicators of metabolic function such as inflammation in the visceral adipose tissue and liver (U.S. EPA, 2019, section 7.1). The ISA concludes that, overall, the collective evidence “is suggestive of, but not sufficient to infer, a causal relationship between short-term PM<sub>2.5</sub> exposure and metabolic effects” (U.S. EPA, 2019, p. 7-11).

##### *PM<sub>2.5</sub> – Nervous system effects*

The evidence reviewed in the 2009 ISA was characterized as "inadequate to infer" a causal relationship between short-term PM<sub>2.5</sub> exposure and nervous system effects (U.S. EPA, 2009), based on a small number of experimental animal studies. Recent studies strengthen the evidence that short-term exposure to PM<sub>2.5</sub> can affect the nervous system (U.S. EPA, 2019, section 8.1). The strongest evidence is provided by experimental studies in mice that show effects on the brain. These toxicological studies demonstrate changes in neurotransmitters in the hypothalamus that are linked to sympathetic nervous system and hypothalamic-pituitary-adrenal (HPA) stress axis activation, as well as upregulation of inflammation-related genes, changes in cytokine levels, and other changes that are indicative of brain inflammation. In addition, an association of short-term PM<sub>2.5</sub> exposure with hospital admissions for Parkinson's disease was observed indicating the potential for exacerbation of neurological diseases. The ISA concludes that, overall, the collective evidence "is suggestive of, but not sufficient to infer, a causal relationship between short-term exposure to PM<sub>2.5</sub> and nervous system effects" (U.S. EPA, 2019, p. 8-15).

#### *UFP – Cardiovascular effects*

In the 2009 ISA, the evidence from toxicological studies, many of which examined exposures to whole diesel exhaust or wood smoke rather than UFP alone, was suggestive of a causal relationship between short-term UFP exposure and cardiovascular effects. Since the 2009 ISA, there have been only a limited number of studies published describing the relationship between short-term UFP exposure and cardiovascular effects. This includes a small number of epidemiologic panel studies that have observed positive associations between short-term exposure to UFPs and measures of HRV (U.S. EPA, 2019, section 6.5.9.1) and markers of coagulation (U.S. EPA, 2019, section 6.5.11.1) although there are also studies that did not report such UFP-related effects. In addition, there is evidence from a single controlled human exposure study indicating decreases in the anticoagulant proteins plasminogen and thrombomodulin in individuals with metabolic syndrome (U.S. EPA, 2019, section 6.5.11.2). There is inconsistent evidence from controlled human exposure and epidemiologic panel studies for endothelial dysfunction, changes in blood pressure, and systemic inflammation following short-term exposure to UFPs. Notably, there is little evidence of an effect when considering short-term UFP exposure on other cardiovascular endpoints as well as cardiovascular-disease emergency department visits or hospital admissions. The assessment of study results across experimental and epidemiologic studies is complicated by differences in the size distributions examined between disciplines and by the nonuniformity in the exposure metrics examined (e.g., particle number concentration, surface area concentration, and mass concentration) (U.S. EPA, 2019, section 1.4.3). When considered as a whole, the ISA concludes that the evidence is "suggestive

of, but not sufficient to infer, a causal relationship between short-term exposure UFP exposure and cardiovascular effects” (U.S. EPA, 2019, p. 6-304).

#### *UFP – Respiratory effects*

A limited number of studies examining short-term exposure to UFPs and respiratory effects were reported in the 2009 ISA, which concluded that the relationship between short-term exposure to UFP and respiratory effects is “suggestive of a causal relationship.” This conclusion was based on epidemiologic evidence indicating associations with combined respiratory-related diseases, respiratory infection, and asthma exacerbation. In addition, personal exposures to ambient UFP were associated with lung function decrements in adults with asthma. The few available experimental studies provided limited coherence with epidemiologic findings for asthma exacerbation. Recent studies add to this evidence base and support epidemiologic evidence for asthma exacerbation and combined respiratory-related diseases but do not rule out chance, confounding, and other biases (U.S. EPA, 2019, section 5.5). For example, associations persist in one epidemiologic study with adjustment for NO<sub>2</sub>, but not in another. Additional supporting evidence, showing decrements in lung function and enhancement of allergic inflammation and other allergic responses, is provided by a controlled human exposure study in adults with asthma and by animal toxicological studies in an animal model of allergic airway disease. For combined respiratory-related diseases, recent findings add consistency for hospital admissions and emergency department visits and indicate lung function changes among adults with asthma or COPD. Uncertainty remains regarding the characterization of UFP exposures and the potential for copollutant confounding in epidemiologic studies, which limits inference about an independent effect of UFP exposures (U.S. EPA, 2019, section 5.5). The ISA concludes that, overall, the evidence is “suggestive of, but not sufficient to infer, a causal relationship between short-term UFP exposure and respiratory effects” (U.S. EPA, 2019, p. 5-303).

#### *UFP- Nervous system effects*

The 2009 ISA reported limited animal toxicological evidence of a relationship between short-term exposure to UFP and nervous system effects, without supporting epidemiologic studies. Several recent experimental studies add to this evidence base. In the current review, the strongest evidence for a relationship between short-term UFP exposure and nervous system effects is provided by animal toxicological studies that show inflammation and oxidative stress in multiple brain regions following exposure to UFP. There is a lack of evidence from epidemiologic studies (U.S. EPA, 2019, section 8.5). The ISA concludes that, overall, the collective evidence is “suggestive of, but not sufficient to infer, a causal relationship between short-term UFP exposure and nervous system effects” (U.S. EPA, 2019, p. 8-86).

### 3.2.1.7 Summary

Based on the evidence assessed in the ISA (U.S. EPA, 2019), and summarized in sections 3.2.1.1 to 3.2.1.6 above, we revisit the policy-relevant questions posed at the beginning of this section:

- **To what extent does the currently available scientific evidence strengthen, or otherwise alter, our conclusions from the last review regarding health effects attributable to long- or short-term fine particle exposures? Have previously identified uncertainties been reduced? What important uncertainties remain and have new uncertainties been identified?**

We consider these questions in the context of the evidence for effects of long- and short-term PM<sub>2.5</sub> exposures.

Studies conducted since the 2009 ISA have broadened our understanding of the health effects that can result from long-term PM<sub>2.5</sub> exposures and have reduced key uncertainties identified in the last review. Recent epidemiologic studies consistently report positive associations between long-term PM<sub>2.5</sub> exposures and a wide range of health outcomes, including total and cause-specific mortality, cardiovascular and respiratory morbidity, lung cancer, and nervous system effects. Such associations have been reported in analyses examining a variety of study designs, approaches to estimating PM<sub>2.5</sub> exposures, statistical models, and long-term exposure windows (i.e., the exposure period that is associated with the health outcome). Recent evidence also includes retrospective studies that demonstrate improvements in health outcomes, including increasing life expectancy, decreasing mortality, or decreasing respiratory effects, as a result of past declines in ambient PM<sub>2.5</sub> concentrations. Recent epidemiologic studies report that associations with mortality (total, cardiovascular, and respiratory) remain relatively unchanged in copollutant models, supporting the independence of these associations from co-occurring gases or coarse PM. Recent studies additionally report that associations (i.e., primarily with mortality) persist in analyses restricted to long-term PM<sub>2.5</sub> exposures in the lower portions of the air quality distribution, and such studies do not identify a threshold below which associations no longer occur. The biological plausibility of health effect associations reported in epidemiologic studies is supported by coherent results from experimental studies. Recent evidence from animal toxicology and/or controlled human exposure studies provides stronger support, compared to previous reviews, for potential biologic pathways by which long-term PM<sub>2.5</sub> exposures could lead to effects on the cardiovascular and respiratory systems, effects on the nervous system, and

to lung cancer.<sup>22 23</sup> In addition to providing insight into potential mechanisms, experimental studies also demonstrate direct effects of PM<sub>2.5</sub> exposures, providing further support for independent effects of particle exposures on health (i.e., not confounded by co-occurring pollutants). When taken together, the evidence available in this review (i.e., U.S. EPA, 2019) reaffirms, and in some cases strengthens, the conclusions from the 2009 ISA regarding the health effects of long-term PM<sub>2.5</sub> exposures.

As with the evidence for effects of long-term exposures, since the 2009 ISA, much progress has been made in assessing key uncertainties in our understanding of health effects associated with short-term PM<sub>2.5</sub> exposures. Recent epidemiologic studies build upon and further reaffirm those studies evaluated in the 2009 PM ISA, providing evidence of positive associations across a range of effects. The independence of the PM<sub>2.5</sub> effects reported in such studies is further supported by the results of copollutant analyses indicating that associations with short-term PM<sub>2.5</sub> remain robust. Some recent studies report that associations persist in analyses that exclude short-term PM<sub>2.5</sub> exposures near the upper end of the air quality distribution and that a threshold below which associations no longer occur is not identifiable from the available data. The plausibility of PM<sub>2.5</sub>-associated mortality is supported by associations with cardiovascular and respiratory morbidity. Direct evidence for PM<sub>2.5</sub> exposure-related cardiovascular effects can also be found in recent controlled human exposure and animal toxicological studies, supported by results of epidemiologic panel studies, reporting that PM<sub>2.5</sub> exposure can result in various cardiovascular effects, including endothelial dysfunction, impaired cardiac function, ST segment depression, thrombosis, conduction abnormalities, and increased blood pressure. Overall, the results from these studies provide coherence and biological plausibility for the consistent results from epidemiologic studies observing positive associations between short-term PM<sub>2.5</sub> concentrations and ischemic heart disease and heart failure, and ultimately cardiovascular mortality. While there are inconsistencies in results across some of the animal toxicological, controlled human exposure, and epidemiologic panel studies, this may be due to substantial differences in study design, study populations, or differences in PM composition across study locations. While recent epidemiologic studies also demonstrate associations between short-term PM<sub>2.5</sub> exposures and respiratory effects, particularly asthma and COPD exacerbations, and while animal toxicological studies provide biological plausibility for these findings, some uncertainty

---

<sup>22</sup> For respiratory effects, nervous system effects, and cancer-related effects animal studies provide support for potential biologic pathways while controlled human exposure studies are more limited.

<sup>23</sup> Animal studies also provide stronger support in this review for effects following exposures to UFP (section 3.2.1), though important uncertainties remain (e.g., inconsistent UFP definitions across studies, various methods of administering UFP exposures in health studies, limited understanding of ambient UFP concentrations and distributions in epidemiologic studies), limiting the potential for these studies to inform policy-relevant conclusions.

remains with respect to the independence of PM<sub>2.5</sub> effects. Thus, when taken together, the evidence available in this review (U.S. EPA, 2019) reaffirms, and in some cases strengthens, the conclusions from the 2009 ISA regarding the health effects of short-term PM<sub>2.5</sub> exposures.

### **3.2.2 Potential At-Risk Populations**

The NAAQS are meant to protect the population as a whole, including groups that may be at increased risk for pollutant-related health effects. In the last review, based on the evidence assessed in the 2009 ISA (U.S. EPA, 2009), the 2011 PA focused on children, older adults, people with pre-existing heart and lung diseases, and those of lower socioeconomic status as populations that are “likely to be at increased risk of PM-related effects” (U.S. EPA, 2011, p. 2-31). In the current review, the ISA cites extensive evidence indicating that “both the general population as well as specific populations and lifestages are at risk for PM<sub>2.5</sub>-related health effects” (U.S. EPA, 2019, p. 12-1). For example, in support of its “causal” and “likely to be causal” determinations, the ISA cites substantial evidence for:

- PM-related mortality and cardiovascular effects in older adults (U.S. EPA, 2019, sections 11.1, 11.2, 6.1, and 6.2);
- PM-related cardiovascular effects in people with pre-existing cardiovascular disease (U.S. EPA, 2019, section 6.1);
- PM-related respiratory effects in people with pre-existing respiratory disease, particularly asthma (U.S. EPA, 2019, section 5.1); and
- PM-related impairments in lung function growth and asthma development in children (U.S. EPA, 2019, sections 5.1 and 5.2; 12.5.1.1).

The ISA additionally notes that stratified analyses (i.e., analyses that directly compare PM-related health effects across groups) provide strong evidence for racial and ethnic differences in PM<sub>2.5</sub> exposures and in PM<sub>2.5</sub>-related health risk. Such analyses indicate that minority populations such as Hispanic and non-Hispanic black populations have higher PM<sub>2.5</sub> exposures than non-Hispanic white populations, thus contributing to adverse health risk in non-white populations (U.S. EPA, 2019, section 12.5.4). Stratified analyses focusing on other groups also suggest that populations with pre-existing cardiovascular or respiratory disease, populations that are overweight or obese, populations that have particular genetic variants, and populations that are of low socioeconomic status could be at increased risk for PM<sub>2.5</sub>-related adverse health effects (U.S. EPA, 2019, Chapter 12).

Thus, the groups at risk of PM<sub>2.5</sub>-related health effects represent a substantial portion of the total U.S. population. In evaluating the primary PM<sub>2.5</sub> standards, an important consideration is the potential PM<sub>2.5</sub>-related public health impacts in these populations.

### 3.2.3 PM<sub>2.5</sub> Concentrations in Key Studies Reporting Health Effects

To inform conclusions on the adequacy of the public health protection provided by the current primary PM<sub>2.5</sub> standards, this section evaluates the PM<sub>2.5</sub> exposures and ambient concentrations (i.e., used as surrogates for exposures in epidemiologic studies) in studies reporting PM<sub>2.5</sub>-related health effects. We specifically consider the following overarching questions:

- **What are the short- or long-term PM<sub>2.5</sub> exposures that have been associated with health effects and to what extent does the evidence support the occurrence of such effects for air quality meeting the current primary PM<sub>2.5</sub> standards?**

In addressing these questions, we emphasize health outcomes for which the ISA has concluded the evidence supports a “causal” or a “likely to be causal” relationship with PM exposures. As discussed above, this includes mortality, cardiovascular effects, and respiratory effects associated with short- or long-term PM<sub>2.5</sub> exposures and cancer and nervous system effects associated with long-term PM<sub>2.5</sub> exposures. While the causality determinations in the ISA are informed by studies evaluating a wide range of PM<sub>2.5</sub> concentrations, this section considers the degree to which the evidence supports the occurrence of PM-related effects at concentrations relevant to informing conclusions on the primary PM<sub>2.5</sub> standards. Section 3.2.3.1 considers the exposure concentrations that have been evaluated in experimental studies and section 3.2.3.2 considers the ambient concentrations in locations evaluated by epidemiologic studies.

#### 3.2.3.1 PM Exposure Concentrations Evaluated In Experimental Studies

In the ISA, the evidence for a particular PM<sub>2.5</sub>-related health outcome is strengthened when results from experimental studies demonstrate biologically plausible mechanisms through which adverse human health outcomes could occur (U.S. EPA, 2015, Preamble p. 20). Two types of experimental studies are of particular importance in understanding the effects of PM exposures: controlled human exposure and animal toxicology studies. In such studies, investigators expose human volunteers or laboratory animals, respectively, to known concentrations of air pollutants under carefully regulated environmental conditions and activity levels. Thus, controlled human exposure and animal toxicology studies can provide information on the health effects of experimentally administered pollutant exposures under highly controlled laboratory conditions (U.S. EPA, 2015, Preamble, p. 11).

In this section, we consider the PM<sub>2.5</sub> exposure concentrations shown to cause effects in controlled human exposure studies and in animal toxicology studies. We particularly consider the consistency of specific PM<sub>2.5</sub>-related effects across studies, the potential adversity of such effects, and the degree to which exposures shown to cause effects are likely to occur in areas meeting the current primary standards. To address these issues, we consider the following question:

- **To what extent does the evidence from controlled human exposure or animal toxicology studies support the potential for adverse cardiovascular, respiratory, or other effects following PM<sub>2.5</sub> exposures likely to occur in areas meeting the current primary standards?**

#### Controlled Human Exposure Studies

As discussed in detail in the ISA (U.S. EPA, 2019, section 6.1), controlled human exposure studies have reported that PM<sub>2.5</sub> exposures lasting from less than one hour up to five hours can impact cardiovascular function.<sup>24</sup> The most consistent evidence from these studies is for impaired vascular function (U.S. EPA, 2019, section 6.1.13.2). In addition, although less consistent, the ISA notes that studies examining PM<sub>2.5</sub> exposures also provide evidence for increased blood pressure (U.S. EPA, 2019, section 6.1.6.3), conduction abnormalities/arrhythmia (U.S. EPA, 2019, section 6.1.4.3), changes in heart rate variability (U.S. EPA, 2019, section 6.1.10.2), changes in hemostasis that could promote clot formation (U.S. EPA, 2019, section 6.1.12.2), and increases in inflammatory cells and markers (U.S. EPA, 2019, section 6.1.11.2). The ISA concludes that, when taken as a whole, controlled human exposure studies demonstrate that short-term exposure to PM<sub>2.5</sub> may impact cardiovascular function in ways that could lead to more serious outcomes (U.S. EPA, 2019, section 6.1.16). Thus, such studies can provide insight into the potential for specific PM<sub>2.5</sub> exposures to cause physiological changes that could increase the risk of more serious effects.

Table 3-2 below summarizes information from the ISA<sup>25</sup> on available controlled human exposure studies that evaluate effects on markers of cardiovascular function following exposures to PM<sub>2.5</sub>, either as concentrated ambient particles (CAP) or in unfiltered versus filtered exhaust.<sup>26</sup>

---

<sup>24</sup> In contrast, controlled human exposure studies provide little evidence for respiratory effects following short-term PM<sub>2.5</sub> exposures (U.S. EPA, 2019, section 5.1, Table 5-18). Therefore, this section focuses on cardiovascular effects evaluated in controlled human exposure studies of PM<sub>2.5</sub> exposure.

<sup>25</sup> Table 3-2 includes the controlled human exposure studies, and the endpoints from each study, that are discussed in the ISA.

<sup>26</sup> Table 3-2 identifies controlled human exposure studies included in the ISA that examine the potential for PM<sub>2.5</sub> exposures to alter markers of cardiovascular function. Studies that focus on specific components of PM<sub>2.5</sub> (e.g., endotoxin), or studies that evaluated PM<sub>2.5</sub> exposures only in the presence of an intervention (e.g., dietary intervention) or other pollutant (e.g., ozone), are not included.

**Table 3-2. Summary of information from PM<sub>2.5</sub> controlled human exposure studies.**

<b>Study</b>	<b>Population</b>	<b>Exposure Details (average concentration; duration)</b>	<b>Results</b>
Bräuner et al., 2008	Healthy adults	10.5 µg/m <sup>3</sup> PM <sub>2.5</sub> (unfiltered) vs below detection (filtered); 24 h	No significant effect on markers of vascular function
Hemmingsen et al., 2015a, Hemmingsen et al., 2015b	Healthy, overweight older adults	24 µg/m <sup>3</sup> (unfiltered) vs 3.0 µg/m <sup>3</sup> (filtered) Copenhagen PM; 5 h	Impaired vascular function and altered heart rate variability; no significant changes in blood pressure or markers of inflammation or oxidative stress
Urch et al., 2010	Non-asthmatic and mild asthmatic adults	64 µg/m <sup>3</sup> CAP (lower exposure); 2 h	No significant change in blood markers of inflammation or oxidative stress
Huang et al., 2012	Healthy adults	90 µg/m <sup>3</sup> CAP; 2 h	No significant changes in heart rate variability
Devlin et al., 2003	Healthy older adults	99 µg/m <sup>3</sup> CAP <sup>27</sup> ; 2 h	Decreased heart rate variability
Hazucha et al., 2013	Adult current and former smokers	109 µg/m <sup>3</sup> CAP; 2 h	No significant changes in markers of inflammation or coagulation
Ghio et al., 2000	Healthy young adults	120 µg/m <sup>3</sup> CAP; 2 h	Increased fibrinogen (coagulation)
Ghio et al., 2003	Healthy young adults	120 µg/m <sup>3</sup> CAP; 2 h	Increased fibrinogen; no significant effect on markers of inflammation
Urch et al., 2010	Non-asthmatic and mild asthmatic adults	140 µg/m <sup>3</sup> CAP (higher exposure); 2 h	Increased blood inflammatory markers
Brook et al., 2009	Healthy adults	149 µg/m <sup>3</sup> CAP; 2 h	Impaired vascular function, increased blood pressure; no significant change in markers of inflammation (compared to filtered air)
Ramanathan et al., 2016	Healthy adults	149 µg/m <sup>3</sup> CAP; 2 h	Decreased anti-oxidant/anti-inflammatory capacity when baseline capacity was low

<sup>27</sup> The published study reports an average CAP concentration of 41 µg/m<sup>3</sup>, but communication with the study authors revealed an error in that reported concentration (Jenkins, 2016).

Sivagangabalan et al., 2011	Healthy adults	150 $\mu\text{g}/\text{m}^3$ CAP; 2 h	Increase in indicator of possible arrhythmia; no significant effect on heart rate
Kusha et al., 2012	Healthy adults	154 $\mu\text{g}/\text{m}^3$ CAP; 2 h	No significant effect on indicator of possible arrhythmia
Gong et al., 2003	Adults with and without asthma	174 $\mu\text{g}/\text{m}^3$ CAP; 2 h	Increased heart rate; No significant effect on indicators of arrhythmia, inflammation, coagulation; inconsistent effects on blood pressure
Gong et al., 2004	Older adults with and without COPD	200 $\mu\text{g}/\text{m}^3$ CAP; 2 h	Decreased heart rate variability, increase in markers of inflammation (without COPD only); inconsistent effect on arrhythmia; no significant effect on markers of blood coagulation
Liu et al., 2015	Healthy adults	238 $\mu\text{g}/\text{m}^3$ CAP; 130 min	Increase in urinary markers of oxidative stress and vascular dysfunction; no significant effect on blood markers of oxidative stress, vascular function, or inflammation
Bellavia et al., 2013	Healthy adults	~242 $\mu\text{g}/\text{m}^3$ CAP; 130 min	Increased blood pressure
Behbod et al., 2013	Healthy adults	~250 $\mu\text{g}/\text{m}^3$ CAP; 130 min	Increase in markers of inflammation
Tong et al., 2015	Healthy older adults	253 $\mu\text{g}/\text{m}^3$ CAP; 2 h	Impaired vascular function and increased blood pressure; no significant change in markers of inflammation or coagulation
Lucking et al., 2011	Healthy young men	320 $\mu\text{g}/\text{m}^3$ (unfiltered) vs 7.2 $\mu\text{g}/\text{m}^3$ (filtered); 1 h	Impaired vascular function and increased potential for coagulation; no significant effect on blood pressure, markers of inflammation, or arterial stiffness
Vieira et al., 2016a, Vieira et al., 2016b	Healthy adults; Heart failure patients	325 $\mu\text{g}/\text{m}^3$ (unfiltered) vs 25 $\mu\text{g}/\text{m}^3$ (filtered) diesel exhaust; 21-min	Increase in marker of potential impairment in heart function, impaired vascular function (heart failure patients); no significant effect on blood pressure, heart rate or heart rate variability, markers of inflammation, markers of coagulation, or arterial stiffness

Most of the controlled human exposure studies in Table 3-2 have evaluated average  $\text{PM}_{2.5}$  exposure concentrations at or above about  $100 \mu\text{g}/\text{m}^3$ , with exposure durations typically up to about two hours. Statistically significant effects on one or more indicators of cardiovascular function are often, though not always, reported following 2-hour exposures to average  $\text{PM}_{2.5}$  concentrations at and above about  $120 \mu\text{g}/\text{m}^3$ , with less consistent evidence for effects following exposures to lower concentrations. Impaired vascular function, the effect identified in the ISA as

the most consistent across studies (U.S. EPA, 2019, section 6.1.13.2), is shown following 2-hour exposures to PM<sub>2.5</sub> concentrations at and above 149 µg/m<sup>3</sup>. Mixed results are reported in the three studies that evaluate longer exposure durations (i.e., longer than 2 hours) and lower PM<sub>2.5</sub> concentrations, with significant effects on some outcomes reported following 5-hour exposures to 24 µg/m<sup>3</sup> in Hemmingsen et al. (2015b), but not for other outcomes following 5-hour exposures in Hemmingsen et al. (2015a) and not following 24-hour exposures to 10.5 µg/m<sup>3</sup> in Bräuner et al. (2008).

To provide some insight into what these studies may indicate regarding the primary PM<sub>2.5</sub> standards, we consider the degree to which 2-hour ambient PM<sub>2.5</sub> concentrations in locations meeting the current primary standards are likely to exceed the 2-hour exposure concentrations at which statistically significant effects are reported in multiple studies for one or more indicators of cardiovascular function. To this end, we refer to Figure 2-14 (Chapter 2, section 2.3.2.2.3), which presents the frequency distribution of 2-hour average PM<sub>2.5</sub> concentrations from all FEM PM<sub>2.5</sub> monitors in the U.S. for 2015-2017. At sites meeting the current primary PM<sub>2.5</sub> standards, most 2-hour concentrations are below 11 µg/m<sup>3</sup>, and almost never exceed 32 µg/m<sup>3</sup>. The extreme upper end of the distribution of 2-hour PM<sub>2.5</sub> concentrations is shifted higher during the warmer months (April to September, denoted by red bars in Figure 2-14), generally corresponding to the period of peak wildfire frequency in the U.S. At sites meeting the current primary standards, the highest 2-hour concentrations measured almost never occur outside of the period of peak wildfire frequency (i.e., 99.9<sup>th</sup> percentile of 2-hour concentrations is 68 µg/m<sup>3</sup> during the warm season). Most of the sites measuring these very high concentrations are in the northwestern U.S. and California (see Appendix A, Figure A-1), where wildfires have been relatively common in recent years. When the typical fire season is excluded from the analysis (blue in Figure 2-14), the extreme upper end of the distribution is reduced (i.e., 99.9<sup>th</sup> percentile of 2-hour concentrations is 59 µg/m<sup>3</sup>).<sup>28</sup>

Thus, while controlled human exposure studies support the plausibility of the serious cardiovascular effects that have been linked with ambient PM<sub>2.5</sub> exposures (U.S. EPA, 2019, Chapter 6), the PM<sub>2.5</sub> exposure concentrations evaluated in most of these studies are well-above the ambient concentrations typically measured in locations meeting the current primary standards. Therefore, controlled human exposure studies are of limited utility in informing conclusions on the adequacy of the public health protection provided by the current standards. Additional controlled human exposure studies that examine longer exposure periods (e.g., 24-hour as in Bräuner et al. (2008); 5-hour as in Hemmingsen et al. (2015b)), or repeated exposures,

---

<sup>28</sup> Similar analyses of 5-hour PM<sub>2.5</sub> concentrations are presented in Appendix A, Figure A-2.

to concentrations typical in the ambient air across much of the U.S. may provide additional insight into this issue in future reviews.

### Animal Toxicology Studies

The ISA relies on animal toxicology studies to support the plausibility of a wide range of PM<sub>2.5</sub>-related health effects. While animal toxicology studies often examine more severe health outcomes and longer exposure durations than controlled human exposure studies, there is uncertainty in extrapolating the effects seen in animals, and the PM<sub>2.5</sub> exposures and doses that cause those effects, to human populations. We consider these uncertainties when evaluating what the available animal toxicology studies may indicate with regard to the current primary PM<sub>2.5</sub> standards.

Most of the animal toxicology studies assessed in the ISA have examined effects following exposures to PM<sub>2.5</sub> concentrations well-above the concentrations likely to be allowed by the current PM<sub>2.5</sub> standards. Such studies have generally examined short-term exposures to PM<sub>2.5</sub> concentrations from 100 to >1,000 µg/m<sup>3</sup> and long-term exposures to concentrations from 66 to >400 µg/m<sup>3</sup> (e.g., see U.S. EPA, 2019, Table 1-2). Two exceptions are a study reporting impaired lung development following long-term exposures (i.e., 24 hours per day for several months prenatally and postnatally) to an average PM<sub>2.5</sub> concentration of 16.8 µg/m<sup>3</sup> (Mauad et al., 2008) and a study reporting increased carcinogenic potential following long-term exposures (i.e., 2 months) to an average PM<sub>2.5</sub> concentration of 17.7 µg/m<sup>3</sup> (Cangerana Pereira et al., 2011). These two studies demonstrate serious effects following long-term exposures to PM<sub>2.5</sub> concentrations similar to the ambient concentrations reported in some PM<sub>2.5</sub> epidemiologic studies (U.S. EPA, 2019, Table 1-2), though still above the ambient concentrations likely to occur in areas meeting the current primary standards. Thus, as is the case with controlled human exposure studies, animal toxicology studies support the plausibility of various adverse effects that have been linked to ambient PM<sub>2.5</sub> exposures (U.S. EPA, 2019), but have not evaluated PM<sub>2.5</sub> exposures likely to occur in areas meeting the current primary standards. Given this, and the additional uncertainty of extrapolating from effects in animals to those in human populations, animal toxicology studies are of limited utility in informing conclusions on the public health protection provided by the current or alternative primary PM<sub>2.5</sub> standards.

#### **3.2.3.2 Ambient PM Concentrations in Locations of Epidemiologic Studies**

As summarized in section 3.2.1 above, epidemiologic studies examining associations between daily or annual average PM<sub>2.5</sub> exposures and mortality or morbidity represent a large part of the evidence base supporting several of the ISA's "causal" and "likely to be causal" determinations. In this section, we consider the ambient PM<sub>2.5</sub> concentrations present in areas where epidemiologic studies have evaluated associations with mortality or morbidity, and what

such concentrations may indicate regarding the primary PM<sub>2.5</sub> standards. The approaches discussed in this section are also summarized above in section 3.1.2.

As noted in section 3.1.2, the use of information from epidemiologic studies to inform conclusions on the primary PM<sub>2.5</sub> standards is complicated by the fact that such studies evaluate associations between distributions of ambient PM<sub>2.5</sub> and health outcomes, and do not identify the specific exposures that cause reported effects. Rather, health effects can occur over the entire distributions of ambient PM<sub>2.5</sub> concentrations evaluated, and epidemiologic studies do not identify a population-level threshold below which it can be concluded with confidence that PM-associated health effects do not occur (U.S. EPA, 2019, section 1.5.3).

In the absence of discernible thresholds, we use two approaches to consider information from epidemiologic studies. In one approach, we evaluate the PM<sub>2.5</sub> air quality distributions reported by key epidemiologic studies (i.e., and used to estimate exposures in these studies) and the degree to which such distributions are likely to occur in areas meeting the current (or alternative) standards (section 3.2.3.2.1). We recognize uncertainty in using this approach to inform conclusions on the primary standards because study-reported PM<sub>2.5</sub> concentrations are not the same as the design values used by the EPA to determine whether areas meet the NAAQS (discussed further below). Therefore, in an additional approach, we calculate study area air quality metrics similar to PM<sub>2.5</sub> design values and consider the degree to which such metrics indicate that study area air quality would likely have met or violated the current or alternative standards during study periods (section 3.2.3.2.2).

To the extent these approaches indicate that health effect associations are based on PM<sub>2.5</sub> air quality likely to have met the current or alternative standards, such standards are likely to allow the daily or annual average PM<sub>2.5</sub> exposures that provide the foundation for reported associations. Alternatively, to the extent reported health effect associations reflect air quality violating the current or alternative standards, there is greater uncertainty in the degree to which such standards would allow the PM<sub>2.5</sub> exposures that provide the foundation for reported associations. The sections below (i.e., 3.2.3.2.1, 3.2.3.2.2) discuss each of these approaches in more detail, and present our key observations based on their application. The potential implications of these observations for the current and alternative primary PM<sub>2.5</sub> standards are discussed below in section 3.4.

#### **3.2.3.2.1 PM<sub>2.5</sub> Air Quality Distributions Associated with Mortality or Morbidity in Key Epidemiologic Studies**

In this section, we consider the PM<sub>2.5</sub> air quality distributions associated with mortality or morbidity in key epidemiologic studies, with a focus on the parts of the distributions over which those studies provide the strongest support for reported associations. As discussed further below, while health effects may occur at PM<sub>2.5</sub> concentrations across the air quality distribution,

epidemiologic studies often provide the strongest support for reported health effect associations over the part of the distribution corresponding to the bulk of the underlying data (i.e., estimated exposures and/or health events). This is the case both for studies of daily PM<sub>2.5</sub> exposures and for studies of annual average PM<sub>2.5</sub> exposures.

Studies of daily PM<sub>2.5</sub> exposures examine associations between day-to-day variation in PM<sub>2.5</sub> concentrations and health outcomes, often over several years. While there can be considerable variability in daily exposures over a multi-year study period, most of the estimated exposures reflect days with ambient PM<sub>2.5</sub> concentrations around the middle of the air quality distributions examined (i.e., “typical” days rather than days with extremely high or extremely low concentrations). Similarly, for studies of annual PM<sub>2.5</sub> exposures, most of the estimated exposures reflect annual average PM<sub>2.5</sub> concentrations around the middle of the air quality distributions examined. In both cases, epidemiologic studies provide the strongest support for reported health effect associations for this middle portion of the PM<sub>2.5</sub> air quality distribution, which corresponds to the bulk of the underlying data, rather than the extreme upper or lower ends of the distribution. Consistent with this, as noted above in section 3.2.1.1, several epidemiologic studies report that associations persist in analyses that exclude the upper portions of the distributions of estimated PM<sub>2.5</sub> exposures, indicating that “peak” PM<sub>2.5</sub> exposures are not disproportionately responsible for reported health effect associations.

An example of the relationship between data density and reported health effect associations is illustrated in Figure 3-2 below (from Lepeule et al., 2012, Figure 1 in supplemental material; U.S. EPA, 2019, Figure 6-26). For the years 1974 to 2009, Lepeule et al. (2012) report a positive and statistically significant association between estimated long-term PM<sub>2.5</sub> exposures and cardiovascular mortality in six U.S. cities. Based on a visual inspection of the concentration-response function reported in this study (i.e., presented in Figure 3-2), 95% confidence intervals are narrowest for long-term PM<sub>2.5</sub> concentrations near the overall mean concentration reported in the study (i.e., 15.9 µg/m<sup>3</sup>). Confidence intervals widen at lower and higher long-term PM<sub>2.5</sub> concentrations, particularly at concentrations ≤ ~10 µg/m<sup>3</sup> and ≥ ~20 µg/m<sup>3</sup>. This widening in the confidence intervals is likely due in part to the comparative lack of data at concentrations approaching the lower and upper ends of the air quality distribution (i.e., exposure estimates are indicated by hash marks on the horizontal axis).

**Figure 3-2. Estimated concentration-response function and 95% confidence intervals between PM<sub>2.5</sub> and cardiovascular mortality in the Six Cities Study (1974-2009) (from Lepeule et al., 2012, supplemental material, figure 1; Figure 6-26 in U.S. EPA, 2019).**

Similar to the information presented in Figure 3-2, other recent studies have also reported that confidence intervals around concentration-response functions are relatively narrow at PM<sub>2.5</sub> concentrations around the overall mean concentrations reported by those studies, likely reflecting high data density in the middle portions of the distributions (e.g., Crouse et al., 2015; Villeneuve et al., 2015; Shi et al., 2016 as discussed in U.S. EPA, 2019, section 11.2.4). Thus, consistent with the approach in the last review (78 FR 3161, January 15, 2013; U.S. EPA, 2011, sections 2.1.3 and 2.3.4.1), we use study-reported means (or medians) of daily and annual average PM<sub>2.5</sub> concentrations as proxies for the middle portions of the air quality distributions, over which studies generally provide strong support for reported associations. As described further below, when considering the PM<sub>2.5</sub> air quality distributions in epidemiologic studies in this section, we focus on PM<sub>2.5</sub> concentrations around these overall means (including concentrations somewhat below means).

To evaluate the PM<sub>2.5</sub> air quality distributions in key studies in this review, we first identify the epidemiologic studies assessed in the ISA that have the potential to be most informative in reaching conclusions on the primary PM<sub>2.5</sub> standards. As for the experimental studies discussed above, we focus on epidemiologic studies that provide strong support for “causal” or “likely to be causal” relationships with PM<sub>2.5</sub> exposures in the ISA. We focus on the health effect associations that are determined in the ISA to be consistent across studies, coherent

with the broader body of evidence (e.g., including animal and controlled human exposure studies), and robust to potential confounding by co-occurring pollutants and other factors. We emphasize multicity studies that examine health effect associations in the U.S. or Canada, as such studies examine potential associations over large geographic areas with diverse atmospheric conditions and population demographics (e.g., U.S. EPA, 2019, sections 11.1 and 11.2). Additionally, studies examining associations outside the U.S. or Canada reflect air quality and exposure patterns that may be less typical of the U.S., and thus less likely to be informative for purposes of reviewing the NAAQS.<sup>29</sup>

Figure 3-3 to Figure 3-6 and Table 3-3 below summarize information from U.S. and Canadian studies that are assessed in the ISA and that meet these criteria. For each study, Figure 3-3 to Figure 3-6 present the cohort and/or geographic area examined, the approach used to estimate PM<sub>2.5</sub> exposures (i.e., monitored versus predicted with hybrid modeling methods<sup>30</sup>), the study years during which health events occurred, the years of PM<sub>2.5</sub> air quality data used to estimate exposures, and the effect estimate<sup>31</sup> with 95% confidence intervals (per 5 µg/m<sup>3</sup> for long-term exposures; 10 µg/m<sup>3</sup> for short-term exposures). When available, these figures also include the overall means (or medians if means are not available) of the short- or long-term PM<sub>2.5</sub> exposure estimates reported by the study.

Figure 3-3 and Figure 3-4 summarize information from studies of long-term PM<sub>2.5</sub> exposures. Figure 3-5 and Figure 3-6 summarize information from studies of short-term PM<sub>2.5</sub> exposures. Table 3-3 summarizes information from the smaller group of retrospective studies that have evaluated the potential for improvements in public health as ambient PM<sub>2.5</sub> concentrations have declined over time. It is important to note that these retrospective studies tend to focus on time periods during which ambient PM<sub>2.5</sub> concentrations were substantially higher than those measured more recently (e.g., see Chapter 2, Figure 2-8).

---

<sup>29</sup> This emphasis on studies conducted in the U.S. or Canada is consistent with the approach in the last review of the PM NAAQS (U.S. EPA, 2011, section 2.1.3).

<sup>30</sup> As discussed further below, and in Chapter 2, hybrid methods incorporate data from several sources, often including satellites and models, in addition to ground-based monitors.

<sup>31</sup> The effect estimates presented in the forest plot figures (Figure 3-3 to Figure 3-6) show the associations of long or short-term PM<sub>2.5</sub> exposures with health endpoints presented either as hazard ratio or odds ratio or relative risk (for which the bold dotted vertical line is at 1), or as per unit or percent change (for which the bold dotted vertical line is at 0).

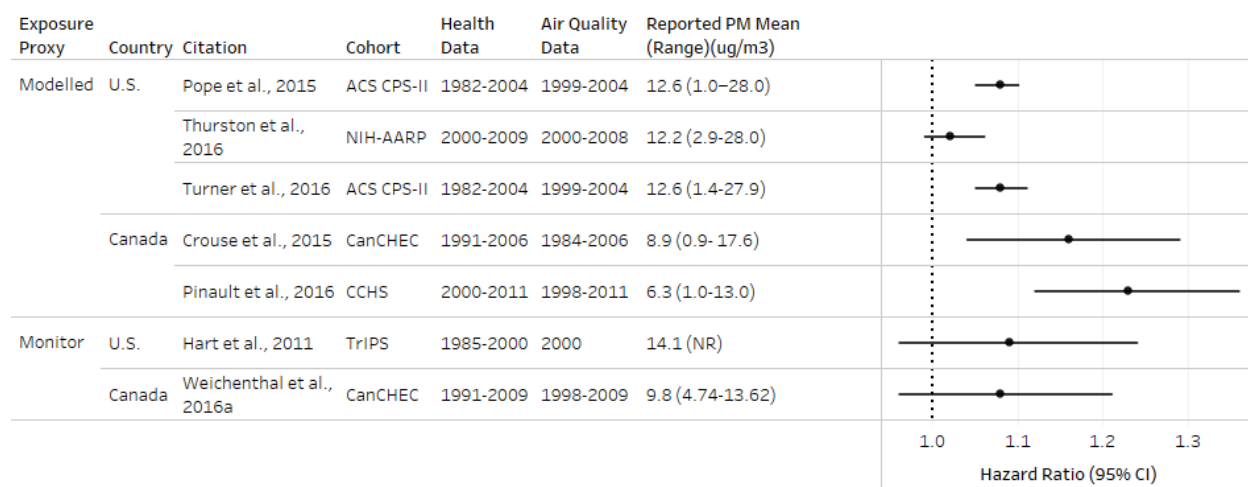

## All-cause mortality

## CVD mortality

## Respiratory mortality

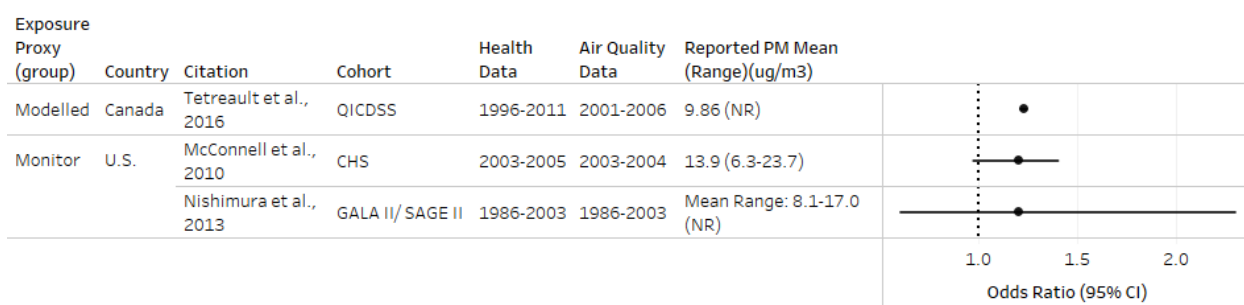

## Lung cancer mortality

**Figure 3-3. Epidemiologic studies examining associations between long-term PM<sub>2.5</sub> exposures and mortality.**

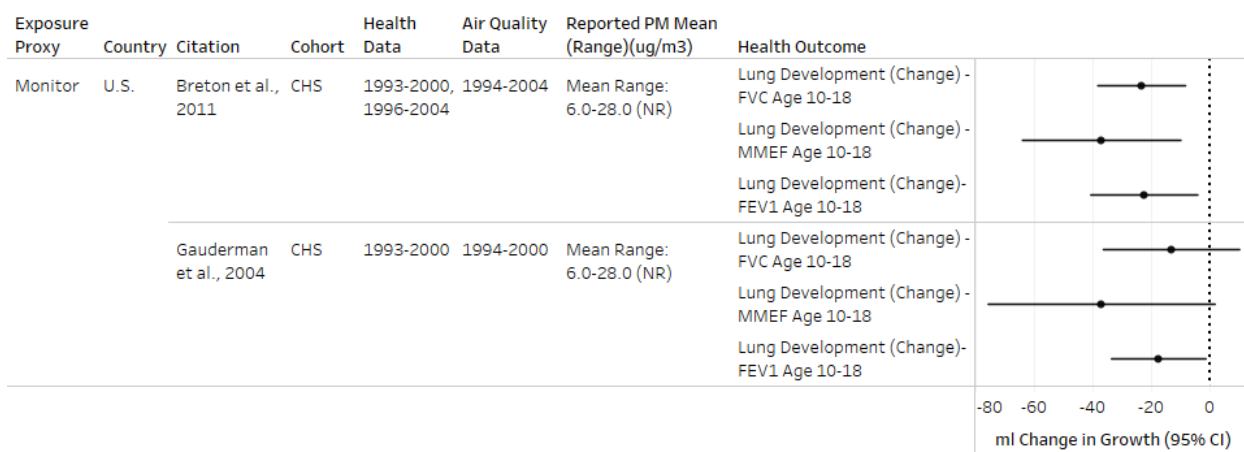

## Asthma incidence

## Lung cancer incidence

## Lung development

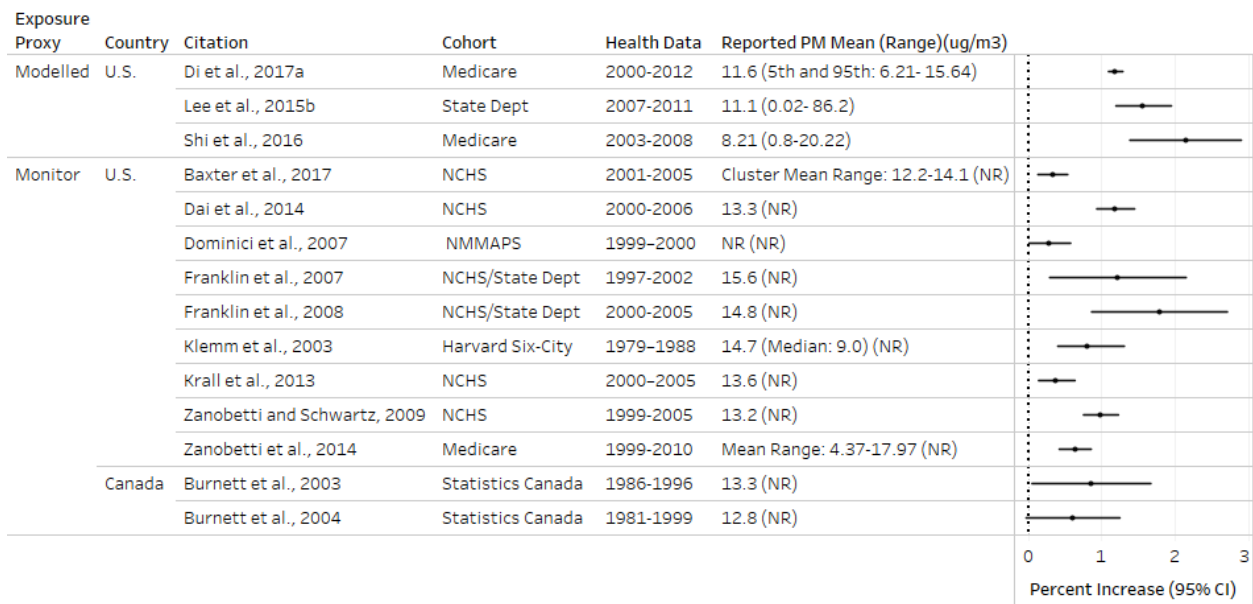

## Lung function

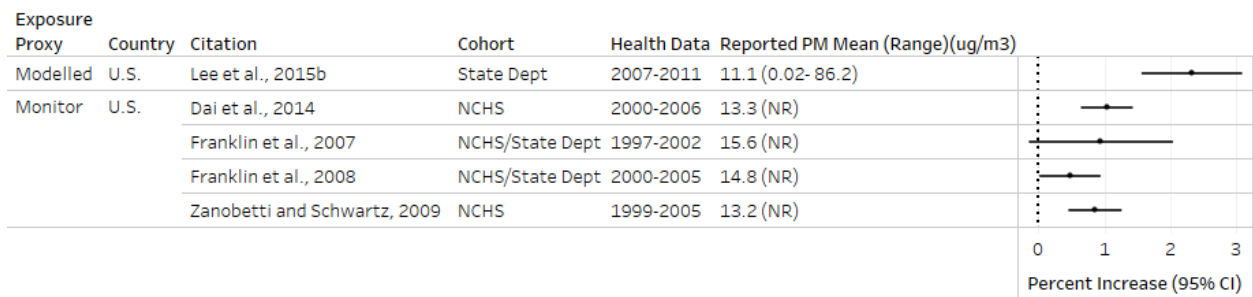

**Figure 3-4. Epidemiologic studies examining associations between long-term PM<sub>2.5</sub> exposures and morbidity.**

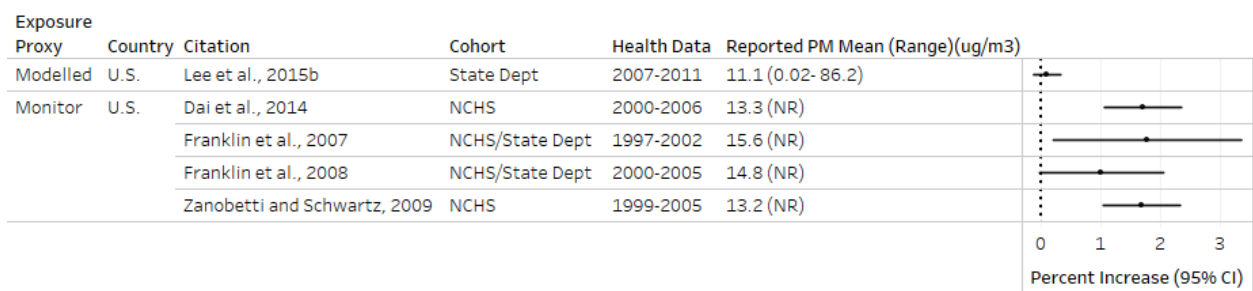

## All-cause mortality

## CVD mortality

## Respiratory mortality

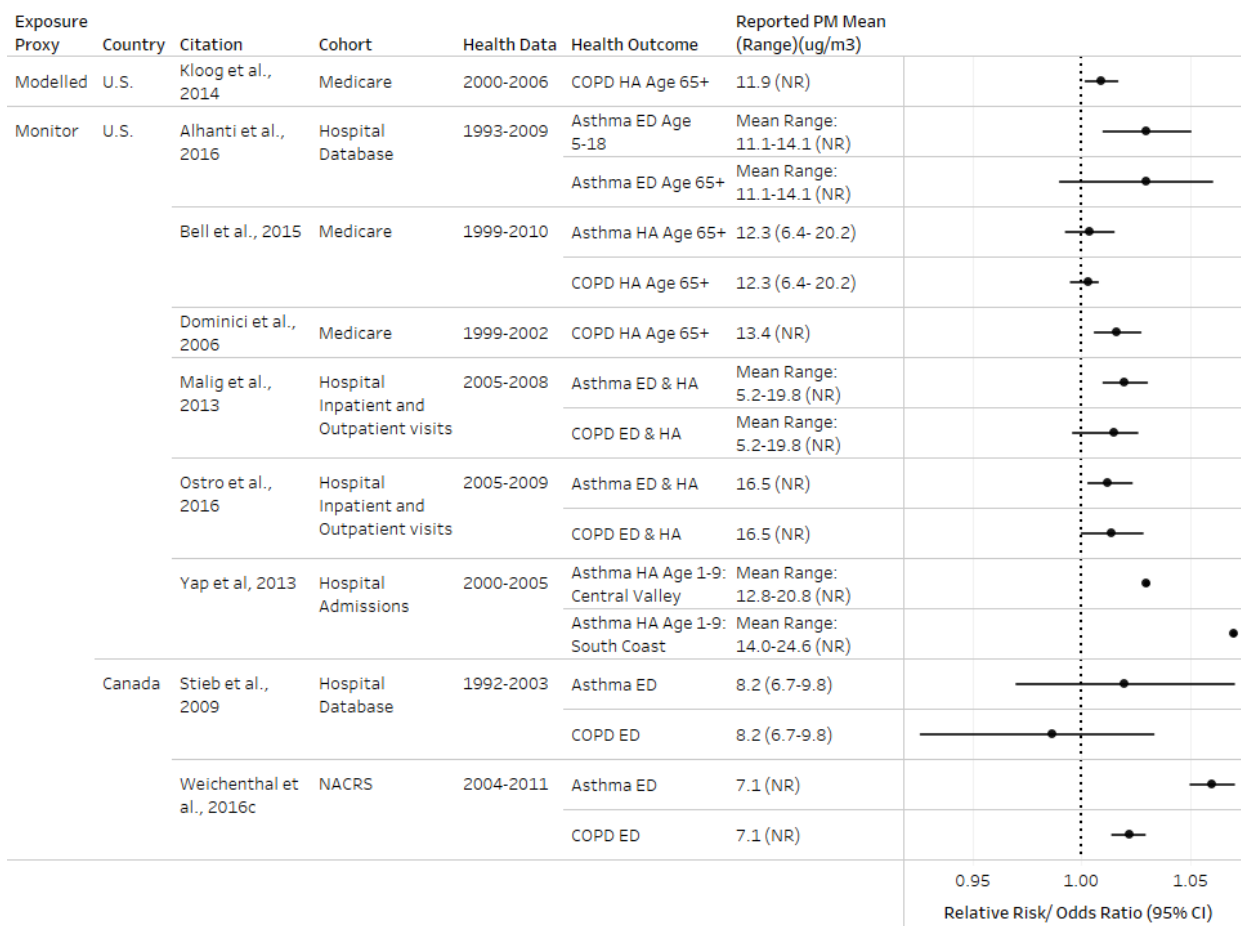

**Figure 3-5. Epidemiologic studies examining associations between short-term PM<sub>2.5</sub> exposures and mortality.<sup>32</sup>**

<sup>32</sup> As noted above, the overall mean PM<sub>2.5</sub> concentrations reported in studies of short-term (24-hour) exposures reflect averages across the study population and over the years of the study. Thus, mean concentrations reflect long-term averages of 24-hour PM<sub>2.5</sub> exposure estimates.

## CVD morbidity

## Respiratory morbidity

**Figure 3-6. Epidemiologic studies examining associations between short-term PM<sub>2.5</sub> exposures and morbidity.**

**Table 3-3. Epidemiologic studies examining the health impacts of long-term reductions in ambient PM<sub>2.5</sub> concentrations.**

Study Reference	Study Area	Years of PM <sub>2.5</sub> Air Quality (monitored)	Starting PM <sub>2.5</sub> Concentrations (mean)	Ending PM <sub>2.5</sub> concentrations (mean)	Study Results
Pope et al. (2009)	211 U.S. counties	1979-1983 compared to 1999-2000	20.6 µg/m <sup>3</sup>	14.1 µg/m <sup>3</sup>	Statistically significant association between declining ambient PM <sub>2.5</sub> and increasing life expectancy
Correia et al. (2013)	545 U.S. counties	2000 compared to 2007	13.2 µg/m <sup>3</sup>	11.6 µg/m <sup>3</sup>	Statistically significant association between declining ambient PM <sub>2.5</sub> and increasing life expectancy
Berhane et al. (2016)	4,602 children in 8 California communities	1992-2000; 1995-2003; 2002-2011	20.5 µg/m <sup>3</sup>	14.4 µg/m <sup>3</sup>	Statistically significant decrease in bronchitic symptoms in 10-year old children with and without asthma
Gauderman et al. (2015)	2,120 children in 5 California communities	1994-1997; 1997-2000; 2007-2010	21.3-31.5 µg/m <sup>3</sup>	11.9-17.8 µg/m <sup>3</sup>	Statistically significant improvements in 4-year growth of lung function

Based on the information in Figure 3-3 to Figure 3-6 and Table 3-3, key epidemiologic studies conducted in the U.S. or Canada indicate generally positive and statistically significant associations between estimated PM<sub>2.5</sub> exposures (short- or long-term) and mortality or morbidity across a wide range of ambient PM<sub>2.5</sub> concentrations. As discussed above, considering the PM<sub>2.5</sub> concentrations around (i.e., somewhat below to somewhat above) the overall means in these studies can provide insight into the part of the air quality distribution over which studies provide the strongest support for reported health effect associations. Evaluating whether such PM<sub>2.5</sub> air quality distributions would be likely to occur in areas meeting the current (or alternative) primary standards can inform conclusions on the degree to which those standards would limit the potential for the long-term and short-term PM<sub>2.5</sub> exposures that provide strong support for reported associations.

For a subset of key epidemiologic studies with available information, we characterize the broader distributions of ambient concentrations, with a particular focus on the concentrations below which data could become appreciably more limited (i.e., below which relatively few estimated exposures, and/or few health events, occurred). As noted above, confidence in reported health effect associations declines for portions of the air quality distribution accounting for

comparatively little data (i.e., concentrations approaching the lower and upper ends of the distribution). Thus, considering the concentrations below which data become relatively sparse can provide insight into the ambient PM<sub>2.5</sub> concentrations below which confidence in reported health effect associations may decrease notably. While there is no single concentration below which we lose confidence in reported associations, consistent with the approach in the last review (U.S. EPA, 2011, section 2.3.4.1), we identify the PM<sub>2.5</sub> concentrations corresponding to the 25<sup>th</sup> and 10<sup>th</sup> percentiles of health data (when available) or exposure estimates to provide insight into the concentrations that comprise the lower quartiles of the air quality distributions.<sup>33</sup>

To frame our evaluation of study-reported PM<sub>2.5</sub> concentrations, we specifically consider the following questions:

- **What are the overall mean PM<sub>2.5</sub> concentrations reported by key epidemiologic studies?**
- **For studies with available information on the broader distributions of exposure estimates and/or health events, what are the PM<sub>2.5</sub> concentrations corresponding to the 25<sup>th</sup> and/or 10<sup>th</sup> percentiles of those data?**

Answers to these questions can provide insight into the range of PM<sub>2.5</sub> concentrations, including those below the overall means, over which key studies provide strong support for reported associations. To this end, Figure 3-7 and Figure 3-8 below present information on the monitored (Figure 3-7) and hybrid model-predicted (Figure 3-8) ambient PM<sub>2.5</sub> concentrations used to estimate PM<sub>2.5</sub> exposures in key epidemiologic studies.

Drawing from the U.S. and Canadian multicity studies in Figure 3-3 to Figure 3-6 above,<sup>34</sup> the studies included in Figure 3-7 and Figure 3-8 are those that report overall mean (or median) PM<sub>2.5</sub> concentrations and for which the years of PM<sub>2.5</sub> air quality data used to estimate exposures overlap entirely with the years during which health events are reported. Regarding this latter issue, the PM<sub>2.5</sub> concentrations reported by studies that estimate exposures from air quality corresponding to only part of the study period, often including only the later years of the health data (e.g., Miller et al., 2007; Hart et al., 2011; Thurston et al., 2013; Weichenthal et al., 2014; Weichenthal et al., 2016a; Pope et al., 2015; Villeneuve et al., 2015; Turner et al., 2016), are not

---

<sup>33</sup> In the last review of the PM NAAQS, the PA identified the long-term PM<sub>2.5</sub> concentrations corresponding to the 25<sup>th</sup> and 10<sup>th</sup> percentiles of health events, or study populations. In doing so, the PA noted that a range of one standard deviation around the mean represents approximately 68% of normally distributed data and, below the mean, falls between the 25<sup>th</sup> and 10<sup>th</sup> percentiles.

<sup>34</sup> Most of the studies included in Table 3-3 above (i.e., studies that examine relationships between declining ambient PM<sub>2.5</sub> concentrations and improving health) report mean ambient PM<sub>2.5</sub> concentrations well-above those in the studies highlighted in Figure 3-3 to Figure 3-6, and well-above the concentrations likely to be informative for conclusions on the current primary PM<sub>2.5</sub> standards. Therefore, our evaluation of mean concentrations focuses on the key studies identified in Figure 3-3 to Figure 3-6.

likely to reflect the full ranges of ambient PM<sub>2.5</sub> concentrations that contributed to reported associations.<sup>35</sup>

Figure 3-7 highlights the overall mean (or median) PM<sub>2.5</sub> concentrations reported in key studies that use ground-based monitors alone to estimate long- or short-term PM<sub>2.5</sub> exposures. For the subset of studies with available information on the broader distributions of underlying data, Figure 3-7 also identifies the study-period mean PM<sub>2.5</sub> concentrations corresponding to the 25<sup>th</sup> and 10<sup>th</sup> percentiles of health events<sup>36</sup> (see Appendix B, Section B.2 for more information).

---

<sup>35</sup> This is an issue only for some studies of long-term PM<sub>2.5</sub> exposures. While this approach can be reasonable in the context of an epidemiologic study evaluating health effect associations with long-term PM<sub>2.5</sub> exposures, under the assumption that spatial patterns in PM<sub>2.5</sub> concentrations are not appreciably different during time periods for which air quality information is not available (e.g., Chen et al., 2016), our interest is in understanding the distribution of ambient PM<sub>2.5</sub> concentrations that could have contributed to reported health outcomes.

<sup>36</sup> That is, 25% of the total health events occurred in study locations with mean PM<sub>2.5</sub> concentrations (i.e., averaged over the study period) below the 25<sup>th</sup> percentiles identified in Figure 3-7 and 10% of the total health events occurred in study locations with mean PM<sub>2.5</sub> concentrations below the 10<sup>th</sup> percentiles identified.

Figure 3-7. Monitored PM<sub>2.5</sub> concentrations in key epidemiologic studies.

We also consider the emerging body of studies that use predicted ambient PM<sub>2.5</sub> concentrations from hybrid modeling methods to estimate long- or short-term PM<sub>2.5</sub> exposures (Figure 3-8, below). As discussed in Chapter 2 of this PA (section 2.3.3), hybrid methods incorporate data from several sources, often including satellites and models in addition to ground-based monitors. Compared to ground-based monitors alone, hybrid methods have the potential to improve the characterization of PM<sub>2.5</sub> exposures in areas with relatively sparse monitoring networks (U.S. EPA, 2019, sections 3.3.2 to 3.3.5).

Figure 3-8 presents overall means of predicted PM<sub>2.5</sub> concentrations for key studies, and the concentrations corresponding to the 25<sup>th</sup> and 10<sup>th</sup> percentiles of estimated exposures or health events<sup>37</sup> when available (see appendix B, section B.3 for additional information).<sup>38</sup> As for the monitor-based studies highlighted above, Figure 3-8 focuses on multicity studies that examine health outcomes supporting “causal” or “likely to be causal” determinations in the ISA and that use air quality data to estimate PM<sub>2.5</sub> exposures for the entire range of years during which health events occurred.<sup>39</sup> In addition to these criteria, we also consider the approach used to validate hybrid model predictions. In particular, the studies included in Figure 3-8 are those for which relatively robust model validation analyses are reported to have been conducted for the full range of years during which PM<sub>2.5</sub> exposures are estimated in the health study (e.g., regional or

---

<sup>37</sup> For most studies in Figure 3-8, 25<sup>th</sup> percentiles of exposure estimates are presented. The exception is Di et al. (2017a), for which Figure 3-8 presents the short-term PM<sub>2.5</sub> exposure estimates corresponding to the 25<sup>th</sup> and 10<sup>th</sup> percentiles of deaths in the study population (i.e., 25% and 10% of deaths occurred at concentrations below these concentrations). In addition, the authors of Di et al. (2017b) provided population-weighted exposure values (Chan, 2019). The 10<sup>th</sup> and 25<sup>th</sup> percentiles of these population-weighted exposure estimates are 7.9 and 9.5 µg/m<sup>3</sup>, respectively.

<sup>38</sup> In addition, 75<sup>th</sup> percentiles of exposure estimates are available for some studies. They are as follows: 14.4 µg/m<sup>3</sup> (Di et al., 2017a), 12.9 µg/m<sup>3</sup> (Di et al., 2017b), 11.7 µg/m<sup>3</sup> (Kloog et al., 2012), 10.7 µg/m<sup>3</sup> (Shi et al. (2016), short-term exposures), 10.0 µg/m<sup>3</sup> (Shi et al. (2016), long-term exposures), 12.9 µg/m<sup>3</sup> (Wang et al., 2017).

<sup>39</sup> All studies that meet the criteria for inclusion in Figure 3-8 were conducted in the U.S.

national 10-fold cross validation performance statistics reported for the same years that exposures are estimated).<sup>40</sup>

---

<sup>40</sup> For example, due to lack of spatial field availability before 1998, Crouse et al. (2015) use median annual PM<sub>2.5</sub> concentrations for the 1998-2006 time period (van Donkelaar et al., 2010; van Donkelaar et al., 2015a; van Donkelaar et al., 2013) to predict exposures during the 1984-2006 period. Similarly, for Pinault et al. (2016), model validation is for 2004 to 2008 (van Donkelaar et al., 2015b) while exposures are estimated for 1998 to 2012. Paciorek et al. (2009), which presents the model validation results for Puett et al. (2009) and Puett et al. (2011), notes that PM<sub>2.5</sub> monitoring was sparse prior to 1999, with many of the available PM<sub>2.5</sub> monitors in rural and protected areas. Therefore, Paciorek et al. (2009) conclude that coverage in the validation set for most of the study period (1988-1998) is poor and that their model strongly underestimates uncertainty (Paciorek et al. (2009), p. 392 in published manuscript). Hystad et al. (2013) used exposure fields developed by calibrating satellite-based PM<sub>2.5</sub> surfaces from a recent period (van Donkelaar et al., 2010) to estimate exposure for the 1975 to 1994 (Hystad et al., 2012). Hystad et al. (2012) noted that a random effect model was used to estimate PM<sub>2.5</sub> based on TSP measurements and metropolitan indicator variables because only small number of PM<sub>2.5</sub> measurements were available, and no measurements were made prior to 1984. Thus, these studies from Figures 3-3 to 3-6 are not included in Figure 3-8.

**Figure 3-8. Hybrid model-predicted PM<sub>2.5</sub> concentrations in key epidemiologic studies.**

Taking the information in Figure 3-7 and Figure 3-8 together, key epidemiologic studies conducted in the U.S. or Canada report generally positive and statistically significant associations between estimated PM<sub>2.5</sub> exposures (short- or long-term) and mortality or morbidity across a wide range of monitored or hybrid-model-predicted ambient PM<sub>2.5</sub> concentrations. With regard to these studies, we particularly note the following:

- For the large majority of key studies, the PM<sub>2.5</sub> air quality distributions that support reported associations are characterized by overall mean (or median) PM<sub>2.5</sub> concentrations ranging from just above 8.0 µg/m<sup>3</sup> to just above 16.0 µg/m<sup>3</sup>. There is substantial overlap between mean concentrations based on monitoring alone and those based on hybrid modeling approaches.
  - Most key studies that use monitors alone to estimate PM<sub>2.5</sub> exposures, and all of the U.S. studies in this group, report overall mean PM<sub>2.5</sub> concentrations at or above 10.7 µg/m<sup>3</sup>.
  - Four Canadian studies that use monitors alone report lower overall mean concentrations. Two of these studies report overall means just above 8.0 µg/m<sup>3</sup> (both report positive and statistically significant associations) and two studies report overall means around 7.0 µg/m<sup>3</sup> (positive and statistically significant association in one of these studies).
  - Most key studies that use hybrid modeling approaches to estimate PM<sub>2.5</sub> exposures report overall mean concentrations at or above 9.6 µg/m<sup>3</sup>. All of these studies were conducted in the U.S. and report positive and statistically significant health effect associations.
  - The hybrid modeling study with the lowest PM<sub>2.5</sub> concentrations reports overall means just above 8.0 µg/m<sup>3</sup> (i.e., Shi et al., 2016). This study reports positive and statistically significant health effect associations with both short- and long-term PM<sub>2.5</sub> exposures.<sup>41</sup>
- Four U.S. studies examine health effect associations in analyses with the highest exposures excluded. Only one of these restricted analyses is reflected in Figure 3-8 (i.e., Di et al., 2017b; “LT exposure < 12 µg/m<sup>3</sup>”). In addition to this study, Lee et al. (2015), Di et al. (2017a) and Shi et al. (2016) also report positive and statistically significant associations in restricted analyses.
  - Lee et al. (2015) reports a positive and statistically significant association in an analysis restricted to zip codes with annual average PM<sub>2.5</sub> concentrations < 12 µg/m<sup>3</sup> and to days with 24-hour average PM<sub>2.5</sub> concentrations < 35 µg/m<sup>3</sup>. This study did not report an overall mean PM<sub>2.5</sub> concentration for the restricted analysis, though it was presumably somewhat below the mean reflected in Figure 3-8 (i.e., 11.1 µg/m<sup>3</sup>).

---

<sup>41</sup> However, the authors report that, for associations with long-term PM<sub>2.5</sub> exposures, most deaths occurred at or above the 75<sup>th</sup> percentile of annual exposure estimates (i.e., 10 µg/m<sup>3</sup>) (see Tables 1 and 2 in published manuscript). Authors did not report this information for their analysis of short-term PM<sub>2.5</sub> exposures.

- Di et al. (2017a) reports a positive and statistically significant association in an analysis restricted to 24-hour PM<sub>2.5</sub> exposure estimates < 25 µg/m<sup>3</sup>. This study did not report an overall mean PM<sub>2.5</sub> concentration for the restricted analysis, though it was presumably somewhat below the mean reflected in Figure 3-8 (i.e., 11.6 µg/m<sup>3</sup>).
- Shi et al. (2016) report positive and statistically significant associations in analyses restricted to annual PM<sub>2.5</sub> exposure estimates < 10 µg/m<sup>3</sup> and in analyses restricted to 24-hour exposure estimates < 30 µg/m<sup>3</sup>. This study does not report the overall mean PM<sub>2.5</sub> concentrations in restricted analyses, though such means are presumably somewhat below those reflected in Figure 3-8 (i.e., 8.1 and 8.2 µg/m<sup>3</sup>).
- For some key studies, information on the broader distributions of PM<sub>2.5</sub> exposure estimates and/or health events is available.
  - In U.S. studies that use monitors alone to estimate PM<sub>2.5</sub> exposures, 25<sup>th</sup> percentiles of health events correspond to mean PM<sub>2.5</sub> concentrations (i.e., averaged over the study period for each study city) at or above 11.5 µg/m<sup>3</sup> and 10<sup>th</sup> percentiles of health events correspond to mean PM<sub>2.5</sub> concentrations at or above 9.8 µg/m<sup>3</sup> (i.e., 25% and 10% of health events, respectively, occur in study locations with mean PM<sub>2.5</sub> concentrations below these values).
  - In the Canadian studies that use monitors alone to estimate PM<sub>2.5</sub> exposures, 25<sup>th</sup> percentiles of health events correspond to mean PM<sub>2.5</sub> concentrations at or above 6.5 µg/m<sup>3</sup> and 10<sup>th</sup> percentiles of health events correspond to mean PM<sub>2.5</sub> concentrations at or above 6.4 µg/m<sup>3</sup>.
  - Of the key studies that use hybrid modeling approaches to estimate long-term PM<sub>2.5</sub> exposures, the ambient PM<sub>2.5</sub> concentrations corresponding to 25<sup>th</sup> percentiles of estimated exposures are 6.2 and 9.1 µg/m<sup>3</sup>. In the one study with data available on the 10<sup>th</sup> percentile of PM<sub>2.5</sub> exposure estimates, the concentration corresponding to that 10<sup>th</sup> percentile is 7.3 µg/m<sup>3</sup>.
  - In studies that use hybrid modeling approaches to estimate short-term PM<sub>2.5</sub> exposures, the ambient concentrations corresponding to 25<sup>th</sup> percentiles of estimated exposures, or health events, are generally at or above 6.4 µg/m<sup>3</sup>. In the one study with lower concentrations, the ambient PM<sub>2.5</sub> concentration corresponding to the 25<sup>th</sup> percentile of estimated exposures is 4.7 µg/m<sup>3</sup>.<sup>42</sup> In the one study with information available on the 10<sup>th</sup> percentile of health events, the ambient PM<sub>2.5</sub> concentration corresponding to that 10<sup>th</sup> percentile is 4.7 µg/m<sup>3</sup>.

The information in Figure 3-7 and Figure 3-8 indicates consistent support for generally positive and statistically significant health effect associations for PM<sub>2.5</sub> air quality distributions

---

<sup>42</sup> As noted above, in this study (Shi et al., 2016), the authors report that most deaths occurred at or above the 75<sup>th</sup> percentile of annual exposure estimates (i.e., 10 µg/m<sup>3</sup>). The short-term exposure estimates accounting for most deaths are not presented in the published study.

characterized by overall mean (or median) concentrations above  $8.0 \mu\text{g}/\text{m}^3$ , with most studies (and all but one U.S. study) reporting overall mean (or median) concentrations at or above  $9.6 \mu\text{g}/\text{m}^3$ . While the ambient  $\text{PM}_{2.5}$  concentrations around these overall means generally reflect the part of the air quality distribution over which studies provide the strongest support for reported  $\text{PM}_{2.5}$  effect estimates, there are uncertainties in using these concentrations to inform conclusions on the primary  $\text{PM}_{2.5}$  standards. These uncertainties are summarized below and their potential implications for conclusions on the current and alternative standards are discussed further in section 3.5.

A key uncertainty in using study-reported mean  $\text{PM}_{2.5}$  concentrations to inform conclusions on the primary  $\text{PM}_{2.5}$  standards is that such concentrations are not the same as the ambient concentrations used by the EPA to determine whether areas meet or violate the PM NAAQS. As discussed above, the overall mean  $\text{PM}_{2.5}$  concentrations reported by key epidemiologic studies reflect averaging of short- or long-term  $\text{PM}_{2.5}$  exposure estimates across locations (i.e., across multiple monitors or across modeled grid cells) and over time (i.e., over several years). In contrast, to determine whether areas meet or violate the NAAQS, the EPA measures air pollution concentrations at individual monitors (i.e., concentrations are not averaged across monitors) and calculates “design values” at monitors meeting appropriate data quality and completeness criteria. For the annual  $\text{PM}_{2.5}$  standard, design values are calculated as the annual arithmetic mean  $\text{PM}_{2.5}$  concentration, averaged over 3 years. For the 24-hour standard, design values are calculated as the 98<sup>th</sup> percentile of the annual distribution of 24-hour  $\text{PM}_{2.5}$  concentrations, averaged over three years (described in Appendix N of 40 CFR Part 50). For an area to meet the NAAQS, all valid design values in that area, including the highest annual and 24-hour monitored values, must be at or below the levels of the standards.

Because of this approach to determining whether areas meet the NAAQS, and because monitors are often required in locations with relatively high  $\text{PM}_{2.5}$  concentrations (section 2.2.3), areas meeting a  $\text{PM}_{2.5}$  standard with a particular level would be expected to have average  $\text{PM}_{2.5}$  concentrations (i.e., averaged across space and over time in the area) somewhat below that standard level. In support of this, analyses of recent air quality in U.S. CBSAs indicate that maximum annual  $\text{PM}_{2.5}$  design values for a given three-year period are often 10% to 20% higher than average monitored concentrations (i.e., averaged across multiple monitors in the same CBSA) (Appendix B, section B.7). The difference between the maximum annual design value and average concentration in an area can be smaller or larger than this range, likely depending on factors such as the number of monitors, monitor siting characteristics, and the distribution of

ambient PM<sub>2.5</sub> concentrations.<sup>43</sup> When using this information to interpret key epidemiologic studies in the context of the primary standards, it is also important to note that such ratios may depend on how the average concentrations in a study are calculated (i.e., averaged across monitors versus across modeled grid cells). Thus, as discussed further in section 3.5 below, when evaluating what the mean PM<sub>2.5</sub> concentrations reported by key epidemiologic studies may indicate regarding the current or alternative PM<sub>2.5</sub> standards, we consider the broader relationships between mean PM<sub>2.5</sub> concentrations, averaged across space and over time, and PM<sub>2.5</sub> design values.<sup>44</sup>

Additional uncertainties in using the PM<sub>2.5</sub> concentrations reported by key epidemiologic studies to inform conclusions on the primary PM<sub>2.5</sub> standards include the following:

- Effects can occur over the full distributions of ambient PM<sub>2.5</sub> concentrations evaluated in epidemiologic studies, and the evidence does not identify a threshold concentration below which PM<sub>2.5</sub>-associated effects no longer occur. Thus, while conclusions on primary standards can be informed by comparing the PM<sub>2.5</sub> air quality distributions present in key studies with the distributions likely to occur in areas meeting the current or alternative standards, studies do not identify specific PM<sub>2.5</sub> exposures that result in health effects or exposures below which effects do not occur.
- For studies that use hybrid model predictions to estimate PM<sub>2.5</sub> exposures, the performance of the recently developed modeling approaches depends on the availability of monitoring data and varies by location. As noted in Chapter 2 (section 2.3.3), factors likely contributing to poorer model performance often coincide with relatively low ambient PM<sub>2.5</sub> concentrations, potentially accounting for the observations that model performance for hybrid models weakens by some metrics with decreasing PM<sub>2.5</sub> concentration and that the normalized variability between predictions based on different hybrid modeling approaches increases with decreasing concentrations. Thus, uncertainty in hybrid model predictions becomes an increasingly important consideration as lower predicted concentrations are considered.

The potential implications of these and other uncertainties for conclusions on the current and alternative primary PM<sub>2.5</sub> standards are discussed below in section 3.4.

### **3.2.3.2.2 PM<sub>2.5</sub> Pseudo-Design Values in Locations of Key Epidemiologic Studies**

In addition to considering the study-reported PM<sub>2.5</sub> concentrations discussed above, we also evaluate study area air quality using metrics more closely related to the design values

---

<sup>43</sup> Given that higher PM<sub>2.5</sub> concentrations have been reported at some near-road monitoring sites, relative to the surrounding area (section 2.3.2.2.2), recent requirements for PM<sub>2.5</sub> monitoring at near-road locations in large urban areas (section 2.2.3) may increase the ratios of maximum annual design values to averaged concentrations in some areas.

<sup>44</sup> As discussed above in section 3.1.2, compared to the annual standard, the potential implications of overall mean PM<sub>2.5</sub> concentrations reported by key epidemiologic studies are less clear for the 24-hour PM<sub>2.5</sub> standard with its 98<sup>th</sup> percentile form (section 3.4).

employed by the EPA to determine whether areas meet or violate the primary PM<sub>2.5</sub> standards. To the extent these metrics suggest that reported health effect associations are based largely on PM<sub>2.5</sub> air quality that would have met the current or alternative standards during study periods, we have greater confidence that those standards would allow the PM<sub>2.5</sub> exposures that provide the basis for reported associations. In contrast, to the extent these metrics suggest that reported health effect associations are based largely on air quality that would have violated the current or alternative standards, there is greater uncertainty in the degree to which those standards would allow the PM<sub>2.5</sub> exposures that provide the basis for reported associations.

To evaluate this issue, we calculate metrics similar to PM<sub>2.5</sub> design values (referred to here as “pseudo-design values”) for the locations and time periods evaluated by key U.S. and Canadian epidemiologic studies. Pseudo-design values are calculated as follows:

- We first identify the study locations with one or more PM<sub>2.5</sub> monitors operating during the study period, and that have sufficient monitoring data available to calculate pseudo-design values.<sup>45</sup>
  - For key studies conducted in the U.S., study locations are defined as the counties included in the study.
  - For key studies conducted in Canada, study locations are defined as the cities included in the study.
- For each monitored study location, we then identify the highest annual and 24-hour PM<sub>2.5</sub> pseudo-design values for each 3-year period of the study and calculate the study-period average of these highest values.
- We also identify the number of people living in each study location or, when available, the number of health events that occurred in each location during the study period.<sup>46</sup>
- To evaluate the percentages of study area populations living in locations likely to have met the current standards over study periods (or the percentages of health events occurring in

---

<sup>45</sup> Pseudo-design values are based on data from both FRM/FEM monitors and from high quality non-FRM/FEM monitors. The non-regulatory data used to calculate pseudo-design values come from monitors typically used for EPA applications like AirNow that are not FRM or FEM. Only monitors with 75% completeness for each of the 12 quarters in a 3-year design value period were included. Sensitivity analyses based only on data from FRM/FEM regulatory monitors gave similar results (Appendix B, section B.5). For the pseudo-design values at the Canadian sites, only sites with 75% completeness for each year of the 3-year design value period were included. These criteria are slightly different than that of actual design values which have strict rounding conventions and substitution tests for sites with less than 75% completeness for each quarter. Additional information on the approach and data sources used to identify pseudo-design values in study locations is provided in Appendix B (section B.4.3).

<sup>46</sup> When available, we use the number of health events in each study location. However, for most key studies, health event data was not available for each study location. For these studies, we evaluate the population living in each study location. Comparison of these approaches in the subset of studies for which health events are available demonstrate that distributions of annual pseudo-design values are comparable for the two approaches (Appendix B, section B.6).

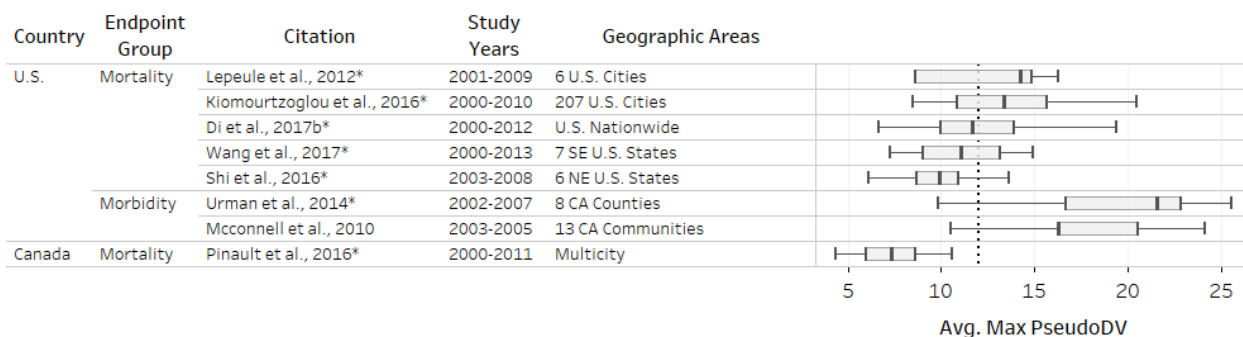

such locations), we identify the percentages in locations with study-period average pseudo-design values at or below the levels of the current annual (Figure 3-9; Appendix B, Tables B-5 and B-6) and 24-hour (Appendix B, Figure B-9) PM<sub>2.5</sub> standards.

In Figure 3-9, whiskers reflect annual PM<sub>2.5</sub> pseudo-design values corresponding to 5<sup>th</sup> and 95<sup>th</sup> percentiles of study area populations (or health events), boxes correspond to the 25<sup>th</sup> and 75<sup>th</sup> percentiles, and the vertical lines inside the boxes correspond to 50<sup>th</sup> percentiles. The vertical dotted line in Figure 3-9 is drawn at 12.0 µg/m<sup>3</sup>, the level of the current annual PM<sub>2.5</sub> standard. For studies with 25<sup>th</sup> percentiles ≤ 12.0 µg/m<sup>3</sup>, at least 25% of the study area population (i.e., in counties or cities with pseudo-design values) lived in locations likely to have met the current annual standard over the study period (or at least 25% of health events occurred in such locations).<sup>47</sup> Similarly, for studies with 50<sup>th</sup> or 75<sup>th</sup> percentiles ≤ 12.0 µg/m<sup>3</sup>, at least 50% or 75% of the study area population, respectively, lived in locations likely to have met the current annual standard over the study period (or at least 50% or 75% of health events occurred in such locations). The percentage of study area populations (or health events) in locations likely to have met the current 24-hour standard over study periods was typically larger than the percentage in locations likely to have met the current annual standard (i.e., Appendix B, Figure B-9).

---

<sup>47</sup> As discussed below, among study locations with averaged PM<sub>2.5</sub> pseudo-design values (i.e., averaged over the study period) at or below 12.0 µg/m<sup>3</sup>, almost all individual 3-year pseudo-design values are also at or below 12.0 µg/m<sup>3</sup> (i.e., 89% for Di et al. (2017b); 98% for Shi et al. (2016)— see Appendix B, section B.9).

### Long-term exposure studies

### Short-term exposure studies

**Figure 3-9. PM<sub>2.5</sub> annual pseudo-design values (in  $\mu\text{g}/\text{m}^3$ ) corresponding to various percentiles<sup>48</sup> of study area populations or health events for studies of long-term and short-term PM<sub>2.5</sub> exposures.<sup>49</sup>**

<sup>48</sup> Asterisks next to study citations denote statistically significant effect estimates.

<sup>49</sup> For most of the studies included in Figure 3-9, pseudo-design values are available for >70% of study area populations (or health events). Exceptions are Kloog et al. (2012), Lee et al. (2015), Pinault et al. (2016), and Wang et al. (2017), with pseudo-design values available for 67%, 56%, 51%, and 65% of study area populations, respectively.

Drawing from the information in Figure 3-9 (and Figure B-9 in Appendix B), we particularly note the following:

- For most of the key studies (i.e., 18 of the 29 in Figure 3-9<sup>50</sup>), about 25% or more of the study area populations (i.e., of those in areas with pseudo-design values) lived in locations with air quality likely to have met the current primary standards over study periods (or about 25% or more of health events occurred in locations with such air quality).
  - For the 15 U.S. studies included in this group, annual pseudo-design values from 8.7 to 11.9  $\mu\text{g}/\text{m}^3$  correspond to 25<sup>th</sup> percentiles of study area populations (or health events).
  - For the three Canadian studies included in this group, annual pseudo-design values from 6.0 to 7.2  $\mu\text{g}/\text{m}^3$  correspond to 25<sup>th</sup> percentiles of study area populations (or health events).
- For nine of the key studies, most of the study area population (i.e., > 50% of those living in areas with pseudo-design values) lived in locations with air quality likely to have met the current standards over study periods (or > 50% of health events occurred in locations with such air quality).
  - For the six U.S. studies included in this group, annual pseudo-design values from 9.9 to 11.7  $\mu\text{g}/\text{m}^3$  correspond to 50<sup>th</sup> percentiles of study area populations (or health events).
  - For the three Canadian studies included in this group, annual pseudo-design values from 7.3 to 7.4  $\mu\text{g}/\text{m}^3$  correspond to 50<sup>th</sup> percentiles of study area populations (or health events).
- For four of the key studies, the large majority of the study area population (i.e., >75% of those living in areas with pseudo-design values) lived in locations with air quality likely to have met the current standards over study periods (or >75% of health events occurred in locations with such air quality).
  - One of these studies (Shi et al., 2016) was conducted in the U.S. In this study, an annual pseudo-design value of 11.0  $\mu\text{g}/\text{m}^3$  corresponds to the 75<sup>th</sup> percentile of the study area population.<sup>51</sup>
  - Three of these studies (Pinault et al., 2016; Weichenthal et al., 2016c; and Weichenthal et al., 2016b) were conducted in Canada. In these studies, annual pseudo-design values from 8.4 to 8.6  $\mu\text{g}/\text{m}^3$  correspond to 75<sup>th</sup> percentiles of the study area populations (or health events).
- For the remaining 11 key studies, the large majority of the study area population (i.e., >75% of those living in areas with pseudo-design values) lived in locations with air quality likely to

---

<sup>50</sup> Shi et al. (2016) separately examined long- and short-term PM<sub>2.5</sub> exposures and, therefore, is included twice in Figure 3-9 and Figure B-9.

<sup>51</sup> In Shi et al. (2016), 85% of all of the study areas with pseudo-design values would likely have met the current annual standard over the entire study period (i.e., annual pseudo-design values for every three-year period examined were  $\leq 12.0 \mu\text{g}/\text{m}^3$ ).

have violated one or both of the current standards during study periods (or >75% of health events occurred in locations with such air quality).

While the information in Figure 3-9 can inform conclusions regarding the degree to which air quality present in study locations and during study periods would likely have met the current primary PM<sub>2.5</sub> standards, there are important uncertainties to consider when using such information to inform conclusions on the primary PM<sub>2.5</sub> standards. These include the following:

- For most key multicity studies, some study locations would likely have met the current primary standards over study periods while others would likely have violated one or both standards. There is uncertainty in how to interpret such studies to inform conclusions on the NAAQS. However, the importance of this uncertainty is lessened for studies that report positive and statistically significant associations in populations that reside almost entirely in areas likely to have met the current standards (e.g., Pinault et al., 2016; Shi et al., 2016; Weichenthal et al., 2016c). This uncertainty is also lessened for key studies that report positive and statistically significant associations in analyses restricted long-term average PM<sub>2.5</sub> concentrations below 12 µg/m<sup>3</sup> (Di et al., 2017b) or 10 µg/m<sup>3</sup> (Shi et al., 2016), which account for about half of the total deaths in these studies (i.e., 54% in Di et al. (2017b), and 49% in Shi et al. (2016)). Effect estimates in these restricted analyses are slightly larger than those based on the entire cohort.
- For each study location, maximum 3-year pseudo-design values are averaged over study periods. Depending on the years of air quality evaluated by the study, for some locations those averages could reflect air quality that violated the current standards during part of the study period and met the current standards during part of the study period. However, analysis of this issue indicates that, among study locations with averaged PM<sub>2.5</sub> pseudo-design values (i.e., averaged over the study period) at or below 12.0 µg/m<sup>3</sup>, almost all individual 3-year pseudo-design values are also at or below 12.0 µg/m<sup>3</sup> (i.e., 89% for Di et al. (2017b); 98% for Shi et al. (2016)— see Appendix B, section B.9).
- Analyses identifying pseudo-design values in study locations necessarily focus on locations with at least one PM<sub>2.5</sub> monitor. While this approach can account for the large majority of study area populations for studies that use monitors alone to estimate PM<sub>2.5</sub> exposures, some recent key epidemiologic studies use hybrid modeling approaches to predict ambient PM<sub>2.5</sub> concentrations in locations with and without nearby ground-based monitors (i.e., Figure 3-8, above). For these studies, PM<sub>2.5</sub> pseudo-design values are not available for unmonitored study locations. For most of the key studies, pseudo-design values are available for locations accounting for more than 70% of the study population. However, for some studies, the percentages of study area populations living in locations with pseudo-design values are lower (Kloog et al., 2012; Lee et al., 2015; Pinault et al., 2016; Wang et al., 2017). To the extent unmonitored areas have generally lower ambient PM<sub>2.5</sub> concentrations than monitored areas, our analyses of pseudo-design values could be biased toward the higher values present in monitored locations.
- PM<sub>2.5</sub> monitoring requirements have changed since the study periods covered by key studies. In particular, PM<sub>2.5</sub> pseudo-design values during study periods do not reflect the near-road PM<sub>2.5</sub> monitors that are now required in many large urban areas (discussed in section 2.3.2.2.2 above). Had current requirements for near-road monitors been in place during study

periods, the maximum pseudo-design values in some counties could have been higher than those identified. Early data from near road monitors indicates that about half of urban areas with near-road monitors measured the highest annual design values at those monitors. Of the CBSAs with highest annual design values at near-road sites, those design values were, on average,  $0.7 \mu\text{g}/\text{m}^3$  higher than at the highest measuring non-near-road sites (range is 0.1 to  $2.0 \mu\text{g}/\text{m}^3$  higher at near-road sites) (Table 2-2 above).

The potential implications of these and other uncertainties for the primary  $\text{PM}_{2.5}$  standards are discussed in section 3.4 below.

### 3.2.3.3 Conclusions from the Evidence

In reaching conclusions based on the evidence considered in section 3.2.3, we revisit the questions posed at the beginning of the section:

- **What are the short- or long-term  $\text{PM}_{2.5}$  exposures that have been associated with health effects and to what extent does the evidence support the occurrence of such effects for air quality meeting the current primary  $\text{PM}_{2.5}$  standards?**

To answer these questions, we draw on information from experimental studies, as discussed in section 3.2.3.1, and information from epidemiologic studies, as discussed in section 3.2.3.2.

With regard to the experimental evidence, we note that available controlled human exposure and animal toxicology studies provide general support for the plausibility of many of the serious health outcomes associated with estimated  $\text{PM}_{2.5}$  exposures in epidemiologic studies (U.S. EPA, 2019, Chapters 5 to 11). However, the  $\text{PM}_{2.5}$  exposure concentrations consistently shown to elicit effects across these studies are considerably higher than the ambient concentrations typically measured in the U.S. in recent years, and higher than the concentrations likely to occur in areas meeting the current primary standards (section 3.2.3.1). A limited number of experimental studies report effects following exposures to lower  $\text{PM}_{2.5}$  concentrations (Mauad et al. (2008); Cangerana Pereira et al. (2011),<sup>52</sup> though still above typical ambient concentrations observed in locations meeting the current standards. Thus, while experimental studies support the plausibility of serious  $\text{PM}_{2.5}$ -associated health effects, these studies provide limited insight into the occurrence of effects following  $\text{PM}_{2.5}$  exposures likely to occur in the ambient air in areas meeting the current primary  $\text{PM}_{2.5}$  standards.

With regard to the epidemiologic evidence, we first note that key studies conducted in the U.S. or Canada indicate positive and often statistically significant associations between estimated

---

<sup>52</sup> Mauad et al. (2008) and Cangerana Pereira et al. (2011) report respiratory and cancer-related effects, respectively, in animals following long-term exposures to  $16.8$  and  $17.7 \mu\text{g}/\text{m}^3$   $\text{PM}_{2.5}$ . Hemmingsen et al. (2015b) reports cardiovascular effects in human volunteers following 5-hour exposures to an average of  $24 \mu\text{g}/\text{m}^3$   $\text{PM}_{2.5}$ . Additionally, the controlled human exposure study by Bräuner et al. (2008) reports no change in markers of cardiovascular function following 24-hour PM exposures to an average  $\text{PM}_{2.5}$  concentration of  $10.5 \mu\text{g}/\text{m}^3$ .

PM<sub>2.5</sub> exposures (short- or long-term) and mortality or morbidity across a broad range of ambient concentrations. These include associations based on PM<sub>2.5</sub> air quality distributions lower than those in key studies from the last review.<sup>53</sup> Based on the information in Figure 3-7 and Figure 3-8, the large majority of key epidemiologic studies in the current review report health effect associations for air quality distributions characterized by overall mean PM<sub>2.5</sub> concentrations ranging from 8.1 µg/m<sup>3</sup> to 16.5 µg/m<sup>3</sup>, with mean concentrations in most of these studies (and all but one key U.S. study) at or above 9.6 µg/m<sup>3</sup>. These include studies that report associations in a wide variety of populations, including studies examining substantial portions of the U.S. population and studies examining groups that may be at comparatively high risk (e.g., older adults, children). These studies employ various study designs and examine a wide variety of health outcomes, geographic areas, approaches to estimating PM<sub>2.5</sub> exposures, and approaches to control for confounding. The evidence for associations at lower ambient concentrations (i.e., means < 8.0 µg/m<sup>3</sup>) is more limited, with two studies conducted in Ontario reporting positive associations (statistically significant in one study) for PM<sub>2.5</sub> air quality distributions characterized by overall mean concentrations around 7.0 µg/m<sup>3</sup> (Weichenthal et al., 2016c; Weichenthal et al., 2016b).

Considering the PM<sub>2.5</sub> concentrations around these overall means can provide insight into the part of the air quality distribution over which studies provide the strongest support for reported health effect associations. Evaluating whether such PM<sub>2.5</sub> air quality distributions would be likely to occur in areas meeting the current (or alternative) primary standards can inform conclusions on the degree to which those standards would limit the potential for the long- and short-term PM<sub>2.5</sub> exposures that support reported health effect associations. However, a limitation of considering study-reported mean PM<sub>2.5</sub> concentrations to inform conclusions on the primary PM<sub>2.5</sub> standards is that such concentrations, by themselves, do not indicate whether study areas would likely have met or violated the current standards (or alternatives).

As discussed above (sections 3.2.3.2.1 and 3.2.3.2.2), the EPA uses design values at individual monitors to determine whether areas meet the NAAQS. Based on analyses of recent air quality in U.S. CBSAs, maximum annual PM<sub>2.5</sub> design values for a given three-year period are often 10% to 20% higher than average concentrations over that period (i.e., averaged across monitors in the same CBSA) (Appendix B, Figure B-7 and Table B-9). These relationships suggest that areas with maximum annual PM<sub>2.5</sub> design values of 12.0 µg/m<sup>3</sup> (i.e., just meeting the current annual standard) are likely to have long-term mean PM<sub>2.5</sub> concentrations (i.e., averaged

---

<sup>53</sup> In the last review key epidemiologic studies supporting “causal” or “likely to be causal” determinations examined distributions of ambient PM<sub>2.5</sub> with overall mean concentrations at or above 12.8 µg/m<sup>3</sup> (U.S. EPA, 2011, Figure 2-8).

across space and over time) that are somewhat below  $12.0 \mu\text{g}/\text{m}^3$  but still higher than the overall means reported by a number of key epidemiologic studies reporting  $\text{PM}_{2.5}$  health effect associations. This indicates that the current standards are likely to allow the distributions of short- and long-term  $\text{PM}_{2.5}$  exposures that are associated with health effects in some key studies.

Another approach to examine the potential implications of key epidemiologic studies for the primary  $\text{PM}_{2.5}$  standards is to consider analyses of  $\text{PM}_{2.5}$  pseudo-design values in locations of those studies, thereby focusing on a study-related air quality metric that is more directly comparable to the levels of the primary  $\text{PM}_{2.5}$  standards. As illustrated in Figure 3-9, and in Figure B-9 in Appendix B, for several key studies with available pseudo-design values (9 of the studies evaluated), most of the study area populations lived in locations with air quality likely to have met both the annual and 24-hour  $\text{PM}_{2.5}$  standards over study periods (or most of health events occurred in such areas). For the U.S. studies in this group, annual pseudo-design values from  $9.9$  to  $11.7 \mu\text{g}/\text{m}^3$  correspond to 50<sup>th</sup> percentiles of study area populations (or health events). That is, 50% of the study area populations lived in locations with pseudo-design values below these concentrations, or 50% of the health events occurred in such locations. For the U.S. study reporting the lowest annual average concentrations (Shi et al., 2016), 75% of the study area population lived in locations with annual pseudo-design values below  $11.0 \mu\text{g}/\text{m}^3$ . For the Canadian studies with the lowest ambient  $\text{PM}_{2.5}$  concentrations, annual pseudo-design values of about  $7.3$  to  $7.4 \mu\text{g}/\text{m}^3$  correspond to 50<sup>th</sup> percentiles of study area populations (or health events), and annual pseudo-design values from  $8.4$  to  $8.6 \mu\text{g}/\text{m}^3$  correspond to 75<sup>th</sup> percentiles.

When the information summarized above is taken together, along with the uncertainties discussed in section 3.2.3.2 above, we reach the conclusion that a number of key epidemiologic studies report positive and statistically significant  $\text{PM}_{2.5}$  health effect associations based largely, or entirely, on air quality that is likely to be allowed by the current primary  $\text{PM}_{2.5}$  standards. Our consideration of the evidence and air quality information to inform conclusions on the primary  $\text{PM}_{2.5}$  standards is discussed further in section 3.4 below.

### **3.3 RISK-BASED CONSIDERATIONS**

To inform conclusions regarding the primary  $\text{PM}_{2.5}$  standards that are “requisite” to protect the public health (i.e., neither more nor less stringent than necessary; section 1.2), it is important to consider the health risks that would be allowed under those standards. For the current standards, this means evaluating  $\text{PM}_{2.5}$ -related health risks in locations with three-year annual  $\text{PM}_{2.5}$  design values of  $12.0 \mu\text{g}/\text{m}^3$  and/or three-year 24-hour design values of  $35 \mu\text{g}/\text{m}^3$  (i.e., neither above nor below the levels of the current standards). Therefore, in addition to our evaluation of  $\text{PM}_{2.5}$  concentrations in locations of key epidemiologic studies (which are based on existing air quality; section 3.2.3.2), we use information from those studies in a risk assessment

that estimates population-level health risks associated with PM<sub>2.5</sub> air quality that has been adjusted to simulate “just meeting” the current standards (i.e., design values equal to 12.0 µg/m<sup>3</sup> and/or 35 µg/m<sup>3</sup>). Given our conclusions based on the evidence (section 3.2.3.3), we also estimate risks associated with PM<sub>2.5</sub> air quality adjusted to simulate “just meeting” alternative annual and 24-hour standards with lower levels. These risk estimates, when considered alongside analyses of the evidence discussed above in section 3.2.3, are meant to inform conclusions on the primary standards that would be requisite to protect the public health against long- and short-term PM<sub>2.5</sub> exposures. Our consideration of estimated risks focuses on addressing the following policy-relevant questions:

- **What are the estimated PM<sub>2.5</sub>-associated health risks for air quality just meeting the current primary PM<sub>2.5</sub> standards?**
- **To what extent are risks estimated to decline when air quality is adjusted to just meet potential alternative standards with lower levels?**
- **What are the uncertainties and limitations in these risk estimates?**

The sections below summarize our approach to estimating risks (section 3.3.1) and the results of the risk assessment (section 3.3.2). Additional detail on the risk assessment is provided in Appendix C.

### **3.3.1 Overview of Approach to Estimating Risks**

Our general approach to estimating PM<sub>2.5</sub>-associated health risks combines concentration-response functions from epidemiologic studies with ambient PM<sub>2.5</sub> concentrations corresponding to air quality scenarios of interest, baseline health incidence data, and population demographics for locations included in the risk assessment. Below we summarize key aspects of the risk modeling approach. Additional detail on the approach is provided in Appendix C (section C.1).

- **Study area selection:** In selecting U.S. study areas for inclusion in the risk assessment, we focus on the following characteristics:
  - *Available ambient monitors:* We focus on areas with relatively dense ambient monitoring networks, where we have greater confidence in adjustments to modeled air quality concentrations in order to simulate “just meeting” the current and alternative primary PM<sub>2.5</sub> standards (air quality adjustments are described in detail in Appendix C, section C.1.4).
  - *Geographical Diversity:* We focus on areas that represent a variety of regions across the U.S. and that include a substantial portion of the U.S. population.
  - *PM<sub>2.5</sub> air quality concentrations:* We balance the value of including a broad array of study areas from across the U.S. against the larger uncertainty associated with air quality adjustments in certain areas. For example, many areas have recent air quality that meets the current primary PM<sub>2.5</sub> standards. Inclusion of such areas in

the risk assessment necessitates an upward adjustment to PM<sub>2.5</sub> air quality concentrations in order to simulate just meeting the current standards. Given uncertainty in how such increases could potentially occur, we select areas (i.e., CBSAs<sup>54</sup>) requiring either a downward adjustment to air quality or a relatively modest upward adjustment (i.e., no more than 2.0 µg/m<sup>3</sup> for the annual standard and 5 µg/m<sup>3</sup> for the 24-hour standard, based on the 2014-2016 design-value period). In addition, as discussed further in Appendix C (section C.1.4), we excluded several areas that appeared to be strongly influenced by exceptional events. Forty-seven urban study areas met these criteria (Figure 3-10 and Appendix C, section C.1.3), including 30 study areas where just meeting the current standards is controlled by the annual standard,<sup>55</sup> 11 study areas where just meeting the current standards is controlled by the daily standard,<sup>56</sup> and 6 areas where the controlling standard differed depending on the air quality adjustment approach (Figure 3-10).<sup>57</sup>

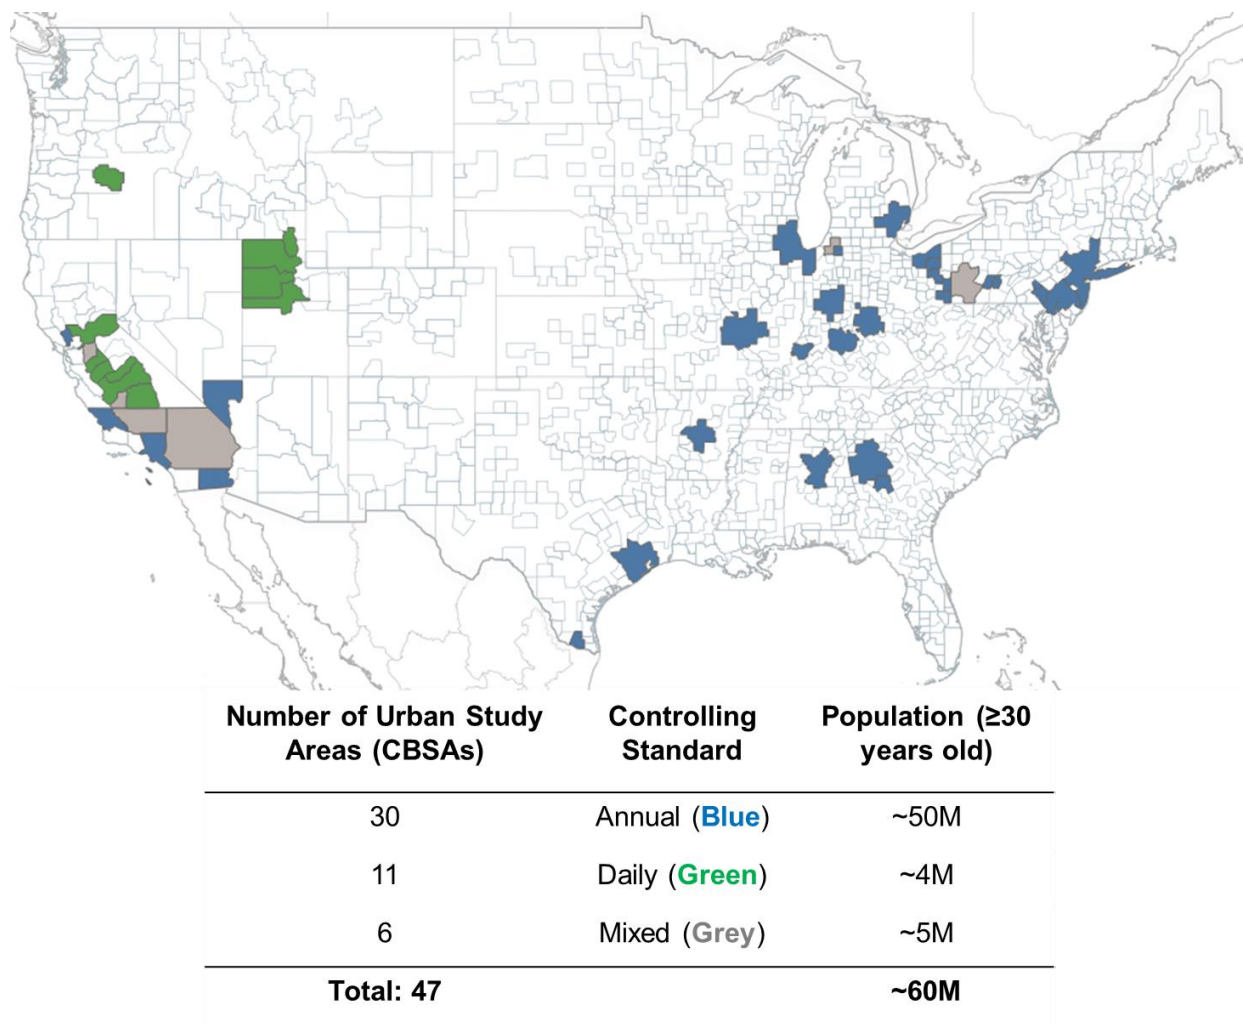

---

<sup>54</sup> CBSAs (core-based statistical areas) can include one or more counties. Each CBSA selected included at least one monitor with valid design values and several CBSAs had more than 10 monitors. See Table C-3 in Appendix C.

<sup>55</sup> For these areas, the annual standard is the “controlling standard” because when air quality is adjusted to simulate just meeting the current or potential alternative annual standards, that air quality also would meet the 24-hour standard being evaluated.

<sup>56</sup> For these areas, the 24-hour standard is the controlling standard because when air quality is adjusted to simulate just meeting the current or potential alternative 24-hour standards, that air quality also would meet the annual standard being evaluated. Some areas classified as being controlled by the 24-hour standard also violate the annual standard.

<sup>57</sup> In these 6 areas, the controlling standard depended on the air quality adjustment method used and/or the standard scenarios evaluated.

**Figure 3-10. Map of 47 urban study areas included in risk modeling.**

- Health outcomes:** The health outcomes evaluated in the risk assessment are (a) total mortality (all-cause and non-accidental), ischemic heart disease mortality, and lung cancer mortality associated with long-term PM<sub>2.5</sub> exposures and (b) total mortality associated with short-term PM<sub>2.5</sub> exposures (Table 3-4 below and Appendix C, section C.1.1). Evidence for these outcomes supports “causal” or “likely to be causal” determinations in the ISA (U.S. EPA, 2019).
- Concentration-response functions:** Concentration-response functions used in this risk assessment are from large, multicity U.S. epidemiologic studies that evaluate PM<sub>2.5</sub> health effect associations (drawn from those identified above in Figures 3-3 to 3-6). The selection of specific epidemiologic studies and concentration-response functions for use in modeling risk is based on criteria that take into account factors such as study design, geographic coverage, demographic groups evaluated, and health endpoints examined. Information from these studies is summarized in Table 3-4. Additional detail regarding the selection of epidemiologic studies and specification of concentration-response functions can be found in Appendix C (section C.1.1).

**Table 3-4. Epidemiologic studies used to estimate PM<sub>2.5</sub>-associated risk.**

- PM<sub>2.5</sub> air quality scenarios evaluated:** We first estimate health risks associated with air quality adjusted to simulate “just meeting” the current primary PM<sub>2.5</sub> standards (i.e., the annual standard with its level of 12.0 µg/m<sup>3</sup> and the 24-hour standard with its level of 35 µg/m<sup>3</sup>). We additionally evaluate the potential for alternative annual standards with levels of 9.0, 10.0 and 11.0 µg/m<sup>3</sup> to reduce estimated risk, relative to the current standards. As discussed above (section 3.1.2), there is greater uncertainty regarding whether a revised 24-hour standard (i.e., with a lower level) would appropriately limit PM<sub>2.5</sub>-associated health risks by limiting the PM<sub>2.5</sub> concentrations that make up the middle portion of the air quality distribution (i.e., where epidemiologic studies provide the strongest support for reported associations). However, we recognize the potential for considering a revised 24-hour standard in this review (discussed below in section 3.5.2.4.2). Therefore, to provide insight into the possible public health implications of a revised 24-hour standard, we also examine an alternative 24-hour standard with a level of 30 µg/m<sup>3</sup>.<sup>58</sup>
- Model-based approach to adjusting air quality:** Air quality modeling is used to simulate just meeting the current standards and alternative standards with levels of 10.0 µg/m<sup>3</sup> (annual) and 30 µg/m<sup>3</sup> (24-hour). The air quality modeling employs a hybrid approach that combines CMAQ-modeled surfaces<sup>59</sup> and ambient monitoring data to generate ambient PM<sub>2.5</sub> estimates for 2015 on a national grid with 12-km horizontal resolution (downscaler). The modeled 2015 PM<sub>2.5</sub> concentrations were then adjusted using one of two approaches<sup>60</sup> for each air quality scenario (discussed in detail in Appendix C, section C.1.4):

<sup>58</sup> We also estimate population risks for recent (i.e., unadjusted) ambient PM<sub>2.5</sub> concentrations (Appendix C).

<sup>59</sup> <https://www.epa.gov/cmaq>

<sup>60</sup> These two modeling approaches provided sensitivity analyses on key aspects of the HHRA and are not additive.

- *Reductions in primarily-emitted PM<sub>2.5</sub> (Pri-PM)*: This approach simulates air quality scenarios of interest by preferentially adjusting modeled directly emitted PM.<sup>61</sup>
- *Reductions in secondarily produced PM<sub>2.5</sub> (Sec-PM)*: This approach simulates air quality scenarios of interest by preferentially adjusting modeled SO<sub>2</sub> and NO<sub>x</sub> precursor emissions to simulate changes in secondarily formed PM<sub>2.5</sub>.<sup>62</sup>
- **Linear interpolation/extrapolation to additional annual standard levels:** In addition to the hybrid modeling approach described above, we also employ linear interpolation and extrapolation to simulate just meeting alternative annual standards with levels of 11.0 (i.e., interpolated between 12.0 and 10.0 µg/m<sup>3</sup>) and 9.0 µg/m<sup>3</sup> (i.e., extrapolated from 12.0 and 10.0 µg/m<sup>3</sup>), respectively (illustrated in Figure 3-11). This interpolation/extrapolation was only performed for the subset of 30 urban study areas where the annual standard was controlling in all air quality scenarios evaluated.

**Figure 3-11. Illustration of approach to adjusting air quality to simulate just meeting annual standards with levels of 11.0 and 9.0 µg/m<sup>3</sup>.**

- **Characterization of variability and uncertainty in the risk estimates:** Both quantitative and qualitative methods have been used to characterize variability and uncertainty in the risk estimates (Appendix C, section C.3), including:
  - *Inclusion of 95 percent confidence intervals for risk estimates:* When modeling risk, we generate confidence intervals for each risk estimate. The confidence intervals reflect the standard error associated with the effect estimate reported in the epidemiologic study that is used to estimate risk.
  - *Sensitivity analyses:* For several of the mortality endpoints, we include a range of risk estimates reflecting epidemiology studies conducted in various populations and using a variety of study designs (e.g., differing in the methods used to estimate exposures and to control for potential confounders). We also estimate risk using two approaches to adjust air quality to simulate just meeting the current and alternative standards (i.e., Pri-PM and Sec-PM adjustment approaches).

<sup>61</sup> In locations for which air quality scenarios cannot be simulated by adjusting modeled directly emitted PM alone, modeled SO<sub>2</sub> and NO<sub>x</sub> precursor emissions are additionally adjusted to simulate changes in secondarily formed PM<sub>2.5</sub> (Appendix C, section C.1.4).

<sup>62</sup> In locations for which air quality scenarios cannot be simulated by adjusting modeled precursor emissions alone, a proportional adjustment of air quality is subsequently applied (Appendix C, section C.1.4).

- *Qualitative uncertainty assessment:* We additionally perform qualitative evaluations of the potential for key sources of uncertainty to impact the magnitude and direction of risk estimates (Appendix C, section C.3.2).

### 3.3.2 Results of the Risk Assessment

This section presents estimates of PM<sub>2.5</sub>-associated mortality risks for urban study areas (additional results are available in Appendix C, section C.2). These results are shown as point estimates with 95 percent confidence intervals for air quality adjusted to simulate just meeting the current, and potential alternative, standards. For alternative standards, we provide tables that include the total or *absolute risk*, the change in or *delta risk*, and the *percent risk reduction*.<sup>63</sup> We also quantify the *percent of baseline incidence*, which estimates the percent of total incidence (i.e., the total public health burden associated with that health effect) that is associated with ambient PM<sub>2.5</sub> exposure.<sup>64</sup> In addition to tables, we also provide figures to illustrate how risks are distributed across annual average ambient PM<sub>2.5</sub> concentrations. Figures present results for IHD mortality associated with long-term PM<sub>2.5</sub> exposures, based on the study by Jerrett et al. (2016). Additional results are presented in Appendix C (section C.2).

The sections below present risk estimates for the full set of 47 modeled urban study areas (section 3.3.2.1), the subset of 30 areas for which the annual PM<sub>2.5</sub> standard is controlling (section 3.3.2.2), and the subset of 11 areas for which the 24-hour PM<sub>2.5</sub> standard is controlling (section 3.3.2.3). Uncertainties in the risk assessment are summarized in section 3.3.2.4.

#### 3.3.2.1 Summary of Risk Estimates for 47 Urban Study Areas

Risk estimates for the 47 urban study areas are presented in Table 3-5 and Table 3-6. Table 3-5 presents absolute risk estimates for air quality just meeting the current primary PM<sub>2.5</sub> standards and alternative standards. Table 3-6 presents differences in estimated risk between air quality just meeting the current standards and air quality just meeting alternative standards. More specifically, the risk estimates presented in the column labeled “Alternative Annual Standard (10 ug/m<sup>3</sup>)” reflect the reductions estimated (compared to the current standards) in the subset of study areas for which the alternative annual standard, with a level of 10.0 ug/m<sup>3</sup>, is controlling. Risk estimates presented in the column labeled “Alternative 24-hour Standard (30 ug/m<sup>3</sup>)” reflect the reductions estimated in the subset of study areas for which the alternative 24-hour standard,

---

<sup>63</sup> *Absolute risk* refers to risk associated with the full increment of exposure associated with either the current or alternative standard. Both *delta risk* and *percent risk reduction* reflect the change in risk in going from the current standard to a specific alternative standard, with delta risk referring to the change in incidence (i.e., premature PM<sub>2.5</sub>-attributable mortality) and percent risk reduction referring to the percent change when comparing risk under the current standard to risk under simulation of an alternative standard.

<sup>64</sup> In other words, the percent of the effect associated with PM<sub>2.5</sub> exposure. For example, risk results estimate that 13-14% of all IHD mortality in 2015 was associated with PM<sub>2.5</sub> exposure (Table 3-5).

with a level of 30 µg/m<sup>3</sup>, is controlling. The smaller reductions estimated for the alternative 24-hour standard reflect the smaller number of study areas controlled by the 24-hour standard and the relatively small population in those areas. Key observations from these results are summarized below.

**Table 3-5. Estimates of PM<sub>2.5</sub>-associated mortality for air quality adjusted to just meet the current or alternative standards (47 urban study areas).**

Drawing from the information in Table 3-5 and Table 3-6, we make the following key observations:

- Air quality adjusted to simulate just meeting the current PM<sub>2.5</sub> standards
  - Long-term PM<sub>2.5</sub> exposures are estimated to be associated with as many as 52,100 premature deaths (all-cause), including 16,800 IHD deaths and 3,950 lung cancer deaths, annually across the 47 study areas (and approximately 54 million people over the age of 30). These estimates account for approximately 3-9% of all-cause, 13-14% of IHD, and 9% of lung cancer mortality in these areas, respectively.<sup>65</sup>
  - Short-term PM<sub>2.5</sub> exposures are estimated to be associated with up to 3,870 deaths annually across the 47 study areas.
  - The approach used to adjust air quality (i.e., Pri-PM and Sec-PM) did not have a substantial impact on overall risk estimates (also see Appendix C, section C.1.4)
- Air quality adjusted to just meet potential alternative standards

<sup>65</sup> Mortality risk estimates for specific endpoints (e.g., IHD and lung cancer) are distinct subsets of total mortality.

- Compared to the current standards, risks are estimated to decrease when air quality is adjusted to just meet an alternative annual standard with a level of 10.0  $\mu\text{g}/\text{m}^3$  or an alternative 24-hour standard with a level of 30  $\mu\text{g}/\text{m}^3$  (Table 3-6).<sup>66</sup>
- Substantially larger risk reductions are estimated in the urban study areas for which the annual standard is controlling than in the study areas for which the 24-hour standard is controlling, reflecting the larger population in the study areas controlled by the annual standard.
- The approach used to adjust air quality did not have a substantial impact on estimated reductions in  $\text{PM}_{2.5}$ -associated mortality.

### 3.3.2.2 Summary of Risk Estimates for a Broader Range of Alternative Annual Standards

This section explores the potential impacts of a range of alternative annual standard levels using interpolation and extrapolation of the modeled  $\text{PM}_{2.5}$  concentrations. Table 3-7 and Table 3-8 below present mortality risk estimates for potential alternative annual standards with levels of 11.0, 10.0, and 9.0  $\mu\text{g}/\text{m}^3$ , based on the subset of 30 urban study areas for which the annual standard is controlling under all air quality scenarios evaluated. Figure 3-12 and Figure 3-13 present distributions of absolute (total) risk associated with air quality adjusted to just meet the current and alternative annual standards and the risk reductions estimated for each alternative annual standard (relative to the current standard), respectively.<sup>67</sup>

---

<sup>66</sup> In most study areas, the risk reductions presented for an annual standard with a level of 10.0  $\mu\text{g}/\text{m}^3$  reflect the difference between air quality with a maximum three-year design value of 12.0  $\mu\text{g}/\text{m}^3$  and air quality with a maximum three-year design value of 10.0  $\mu\text{g}/\text{m}^3$ . Similarly, in most study areas, the risk reduction presented for a 24-hour standard with a level of 30  $\mu\text{g}/\text{m}^3$  reflects the difference between air quality with a maximum three-year design value of 35  $\mu\text{g}/\text{m}^3$  and air quality with a maximum three-year design value of 30  $\mu\text{g}/\text{m}^3$ . However, in a small number of study areas, the “starting concentration” for the annual standard are below 12.0  $\mu\text{g}/\text{m}^3$  (four study areas: Riverside-San Bernardino-Ontario, CA; Stockton-Lodi, CA; Bakersfield, CA; and Hanford-Corcoran, CA) or the starting concentration for the 24-hr standard are below 35  $\mu\text{g}/\text{m}^3$  (two study areas: Pittsburgh, PA and South Bend-Mishawaka, IN-MI:). This is because, in these areas, the controlling standard for air quality adjusted to just meet the current standards is different from the controlling standard for air quality adjusted to simulate just meeting the alternatives evaluated.

<sup>67</sup> As noted above, Figure 3-12 and Figure 3-13 present estimates of IHD mortality associated with long-term  $\text{PM}_{2.5}$  exposures, based on the study by Jerrett et al. (2016).

**Table 3-7. Estimates of PM<sub>2.5</sub>-associated mortality for the current and potential alternative annual standards in the 30 study areas where the annual standard is controlling.**

Endpoint	Study	Air quality simulation approach*	Current Standand Absolute Risk (12/35 µg/m³)	CS (12/35 µg/m3) % of baseline**	Alternative Annual Standard (absolute risk)

**Figure 3-12. Distribution of absolute risk estimates (PM<sub>2.5</sub>-associated mortality) for the current and alternative annual standards for the subset of 30 urban study areas where the annual standard is controlling (blue and green lines represent the Pri-PM<sub>2.5</sub> and Sec-PM<sub>2.5</sub> estimates, respectively).<sup>68</sup>**

<sup>68</sup> In Figure 3-12, risk estimates are rounded toward zero into whole PM<sub>2.5</sub> concentration values (e.g., risk estimate at 10 µg/m³ includes risk occurring at 10.0-10.9 µg/m³). Risk is estimated in this figure using Jerrett et al., 2016. For each standard, a small amount of risk is estimated at concentrations higher than the level of the annual standard (e.g., some risk is estimated at an average concentration of 13 µg/m³ when air quality is adjusted to just meet the current standard). This can result because risk estimates are for a single year (i.e., 2015) within the 3-year design value period (i.e., 2014 to 2016). While the three-year average design value is 12.0 µg/m³, a single year can have grid cells with annual average concentrations above or below 12.0 µg/m³.

Annual Standard Change	Simulation Method	Annual PM Concentration (1 $\mu\text{g}/\text{m}^3$ bins)												Total

**Figure 3-13. Distribution of the difference in risk estimates between the current annual standard (level of 12.0  $\mu\text{g}/\text{m}^3$ ) and alternative annual standards with levels of 11.0, 10.0, and 9.0  $\mu\text{g}/\text{m}^3$  for the subset of 30 urban study areas where the annual standard is controlling.<sup>69</sup>**

Drawing from the information in Table 3-7, Table 3-8, Figure 3-12, and Figure 3-13, we note the following key observations:

- For air quality just meeting the current annual standard, in the subset of 30 study areas in which the annual standard is controlling, long-term  $\text{PM}_{2.5}$  exposures are estimated to be associated with as many as 45,000 total deaths and 14,600 IHD deaths annually, accounting for approximately 3-9% and 13-14% of baseline mortality, respectively. The majority of this estimated risk is associated with annual average  $\text{PM}_{2.5}$  concentrations from 10 to 12  $\mu\text{g}/\text{m}^3$  (Figure 3-12).
- Compared to the current annual standards, air quality adjusted to meet alternative annual standards with lower levels is associated with reductions in estimated IHD mortality risk across the 30 study areas (i.e., 7 to 9% reduction for a level of 11.0  $\mu\text{g}/\text{m}^3$ ; 14 to 18% reduction for a level of 10.0  $\mu\text{g}/\text{m}^3$ ; 21 to 27% reduction for a level of 9.0  $\mu\text{g}/\text{m}^3$ ) (Table 3-8 and Figure 3-12).
- The magnitude of estimated risk reduction increases as alternative annual standards with lower levels are simulated, and these estimated risk reductions are associated with lower ambient  $\text{PM}_{2.5}$  concentrations. Specifically, for air quality adjusted to simulate just meeting an annual standard with a level of 11.0  $\mu\text{g}/\text{m}^3$ , the majority of risk reduction occurs in grid cells with ambient  $\text{PM}_{2.5}$  concentrations between 9 and 11  $\mu\text{g}/\text{m}^3$ ; for air quality adjusted to simulate just meeting an annual standard with a level of 10.0  $\mu\text{g}/\text{m}^3$ , the majority of risk reduction occurs in grid cells with ambient  $\text{PM}_{2.5}$  concentrations between 8 and 10  $\mu\text{g}/\text{m}^3$ ; and for air quality adjusted to simulate just meeting an annual standard with a level of 9.0  $\mu\text{g}/\text{m}^3$ , the majority of risk reduction occurs in grid cells with ambient  $\text{PM}_{2.5}$  concentrations between 7 and 9  $\mu\text{g}/\text{m}^3$ <sup>70</sup> (Figure 3-13).

<sup>69</sup> Risks are presented as integers rounded to three significant digits and aggregated into 1  $\mu\text{g}/\text{m}^3$  bins. Bins begin at the whole number value indicated and include values up to, but not including, the next whole number (e.g., risk occurring at PM concentrations of 6.00 to 6.99 are shown in the bin at 6). Risk is estimated in this figure using Jerrett et al. (2016).

<sup>70</sup> Compared to adjusting primary  $\text{PM}_{2.5}$  emissions, adjustment of PM precursor emissions resulted in substantially larger estimated risk reductions at 7  $\mu\text{g}/\text{m}^3$ .

### 3.3.2.3 Summary of Risk Estimates for a Potential Alternative 24-Hour Standard

Table 3-9 presents risk estimates and key observations for the subset of 11 urban study areas in which the 24-hour standard controls the simulated attainment of all modeled standard levels. For air quality just meeting the current 24-hour standard, long-term PM<sub>2.5</sub> exposures are estimated to be associated with as many as 2,970 total deaths and 870 IHD deaths annually, accounting for approximately 3-8% and 12-13% of baseline mortality, respectively. Compared to the current standard, air quality just meeting an alternative 24-hour standard with a level of 30 µg/m<sup>3</sup> is associated with reductions in estimated risk of 14 to 18%.

**Table 3-9. Estimates of PM<sub>2.5</sub>-associated mortality for the current 24-hour standard, and an alternative, in the 11 study areas where the 24-hour standard is controlling.**

### 3.3.2.4 Variability and Uncertainty in Risk Estimates

We characterize variability and uncertainty associated with risk estimates using several quantitative and qualitative approaches, as described in detail in Appendix C (section C.3). Approaches to addressing key uncertainties include the following:

- **Evaluating various effect estimates for the same health endpoint:** In some instances, the effect estimate used has only a small impact on risk estimates (i.e., IHD mortality using effect estimates from Jerrett et al., 2016) versus Pope et al., 2015), see Table 3-5). By contrast, for other mortality endpoints, such as all-cause mortality associated with long-term exposures (e.g., Di et al., 2017b) and Pope et al. (2015) versus Thurston et al., 2016)), the use of different effect estimates can have a larger impact (Table 3-5). The degree to which

different concentration-response functions result in different risk estimates could reflect differences in study design and/or study populations evaluated, as well as other factors.

- **Evaluating multiple methods for simulating air quality scenarios:** The approach used to adjust air quality (i.e., Pri-PM and Sec-PM adjustments) has little impact on overall estimates of risk (e.g., see Table 3-5). However, the adjustment approach has a larger impact on the distribution of risk reductions, particularly for the level of 9.0  $\mu\text{g}/\text{m}^3$  (Figure 3-13).
- **Characterizing the 95 percent confidence intervals associated with risk estimates:** There is considerable variation in the range of confidence intervals associated with the point estimates generated for this analysis (see Table 3-5), with some health endpoint/study combinations displaying substantially greater variability than others (e.g., short-term PM<sub>2.5</sub> exposure and all-cause mortality based on effect estimates from Ito et al. (2013) versus long-term PM<sub>2.5</sub> exposure IHD mortality estimates based on Jerrett et al. (2016)). There are a number of factors potentially responsible for the varying degrees of statistical precision in effect estimates, including sample size, exposure measurement error, degree of control for confounders/effect modifiers, and variability in PM<sub>2.5</sub> concentrations.
- **Qualitative assessment of additional sources of uncertainty:** Based in part on WHO (2008) guidance and on guidance documents developed by the EPA (U.S. EPA, 2001, U.S. EPA, 2004), we have also completed a qualitative characterization of sources of uncertainty including an assessment of both the magnitude and direction of impact of those uncertainties on risk estimates. The classification of the magnitude of impact for sources of uncertainty includes three levels: (a) low (unlikely to produce a sufficient impact on risk estimates to affect their interpretation), (b) medium (potential to have a sufficient impact to affect interpretation), and (c) high (likely to have an impact sufficient to affect interpretation). For several of the sources, we provide a classification between these levels (e.g., low-medium, medium-high).<sup>71</sup> Sources of uncertainty given at least a medium classification include the following (from Appendix C, Table C-32):<sup>72</sup>
  - **Use of air quality modeling to adjust PM<sub>2.5</sub> concentrations:** The baseline and adjusted air quality concentration fields were developed using modeling to fill spatial and temporal gaps in monitoring and explore “what if” scenarios. State-of-the-science modeling methods were used, but modeling-related biases and errors introduce uncertainty into the PM<sub>2.5</sub> concentration estimates. In addition, due to the national scale of the assessment, scenarios are based on changing modeled emissions of primary PM<sub>2.5</sub> or NO<sub>x</sub> and SO<sub>2</sub> from all anthropogenic sources throughout the U.S. by fixed percentages. Although this approach tends to target the key sources in each area, it does not tailor

---

<sup>71</sup> Additional information is available in Appendix C, section C.3.

<sup>72</sup> We also identified several additional factors judged to have less than a medium classification of impact on the risk estimates generate, including: (a) the temporal mismatch between ambient air quality data characterizing exposure and mortality in long-term exposure-related epidemiology studies, (b) compositional and source differences in PM, (c) exposure measurement error in epidemiology studies assessing the relationship between mortality and exposure to ambient PM<sub>2.5</sub>, (d) lag structure in short-term exposure-related mortality epidemiology studies, and (e) assumed causal association between PM and mortality that supports modeling changes in risk associated with future changes in ambient PM<sub>2.5</sub>. See Table C-32 in Appendix C for additional discussion of these sources of uncertainty.

emission changes to specific periods or sources. The two adjustment cases span a wide range of emission conditions, but these cases are necessarily a subset of the full set of possible emission scenarios that could be used to adjust PM<sub>2.5</sub> concentrations to simulate “just meeting” standards.

- **Use of linear interpolation/extrapolation to adjust air quality:** The use of interpolation and extrapolation to simulate just meeting annual standards with levels of 11.0 and 9.0 µg/m<sup>3</sup>, respectively, does not fully capture potential non-linearities associated with real-world changes in air quality.
- **Potential confounding of the PM<sub>2.5</sub>-mortality effect:** Factors are considered potential confounders if demonstrated in the scientific literature to be related to health effects and correlated with PM<sub>2.5</sub>. Omitting potential confounders from analyses could either increase or decrease the magnitude of PM<sub>2.5</sub> effect estimates (e.g., Di et al., 2017b, Figure S2 in Supplementary Materials). Thus, not accounting for confounders can introduce uncertainty into effect estimates and, consequently, into the risk estimates generated using those effect estimates. Confounders vary according to study design, exposure duration, and health effect. For studies of short-term exposures, confounders may include meteorology (e.g., temperature, humidity), day of week, season, medication use, allergen exposure, and long-term temporal trends. For studies of long-term exposures, confounders may include socioeconomic status, race, age, medication use, smoking status, stress, noise, and occupational exposures. While various approaches to control for potential confounders have been adopted across the studies used in the risk assessment, and across the broader body of PM<sub>2.5</sub> epidemiologic studies assessed in the ISA, no individual study adjusts for all potential confounders.
- **Potential for exposure error:** Epidemiologic studies have employed a variety of approaches to estimate population-level PM<sub>2.5</sub> exposures (e.g., stationary monitors, hybrid modeling approaches). These approaches are based on using measured or predicted ambient PM<sub>2.5</sub> concentrations as surrogates for population exposures. As such, exposure estimates in epidemiologic studies are subject to exposure error. The ISA notes that, while bias in either direction can occur, exposure error tends to result in underestimation of health effects in epidemiologic studies of PM exposure (U.S. EPA, 2019, section 3.5). Consistent with this, a recent study by Hart et al. (2015) reports that correction for PM<sub>2.5</sub> exposure error using personal exposure information results in a moderately larger effect estimate for long-term PM<sub>2.5</sub> exposure and mortality (though with wider confidence intervals). This error in the underlying epidemiologic studies contributes to uncertainty in the risk estimates that are based on concentration-response relationships in those studies. Beyond the exposure error in epidemiologic studies themselves, the use of a different approach to represent exposures in the risk assessment (i.e., 12 x 12 km gridded surface based on modeling) could introduce additional error into risk estimates.
- **Shape of the concentration-response relationship at low ambient PM concentrations:** Interpreting the shapes of concentration-response

relationships, particularly at PM<sub>2.5</sub> concentrations near the lower end of the air quality distribution, can be complicated by relatively low data density in the lower concentration range, the possible influence of exposure measurement error, and variability among individuals with respect to air pollution health effects. These sources of variability and uncertainty tend to smooth and “linearize” population-level concentration-response functions, and thus could obscure the existence of a threshold or nonlinear relationship (U.S. EPA, 2015, section 6.c).

### **3.3.3 Conclusions from the risk assessment**

The risk assessment estimates that the current primary PM<sub>2.5</sub> standards could allow a substantial number of PM<sub>2.5</sub>-associated deaths in the U.S. For example, when air quality in the 47 study areas is adjusted to simulate just meeting the current standards, the risk assessment estimates from about 16,000 to 17,000 long-term PM<sub>2.5</sub> exposure-related deaths from ischemic heart disease in a single year (i.e., confidence intervals range from about 12,000 to 21,000 deaths). The absolute numbers of estimated PM<sub>2.5</sub>-associated deaths vary widely across exposure durations, endpoints, populations, and concentration-response functions. In addition, limitations in the underlying data and approaches (summarized above) lead to uncertainty regarding absolute estimates of PM<sub>2.5</sub>-associated risk for any given air quality scenario. However, the general magnitude of risk estimates supports the potential for significant public health impacts in locations meeting the current primary PM<sub>2.5</sub> standards. This is particularly the case given that the large majority of PM<sub>2.5</sub>-associated deaths for air quality just meeting the current standards are estimated at annual average PM<sub>2.5</sub> concentrations from about 10 to 12 µg/m<sup>3</sup>. These annual average PM<sub>2.5</sub> concentrations fall well-within the range of long-term average concentrations over which key epidemiologic studies provide strong support for reported positive and statistically significant PM<sub>2.5</sub> health effect associations.

Compared to the current annual standard, meeting a revised annual standard with a lower level is estimated to reduce PM<sub>2.5</sub>-associated health risks by about 7 to 9% for a level of 11.0 µg/m<sup>3</sup>, 14 to 18% for a level of 10.0 µg/m<sup>3</sup>, and 21 to 27% for a level of 9.0 µg/m<sup>3</sup>. As the magnitude of estimated risk reductions increases at lower levels, these estimated risk reductions are associated with lower ambient PM<sub>2.5</sub> concentrations. Specifically, for air quality adjusted to simulate just meeting an annual standard with a level of 11.0 µg/m<sup>3</sup>, the majority of risk reduction occurs at annual average PM<sub>2.5</sub> concentrations between 9 and 11 µg/m<sup>3</sup>; for air quality adjusted to simulate just meeting an annual standard with a level of 10.0 µg/m<sup>3</sup>, the majority of risk reduction occurs at PM<sub>2.5</sub> concentrations between 8 and 10 µg/m<sup>3</sup>; and for air quality adjusted to simulate just meeting an annual standard with a level of 9.0 µg/m<sup>3</sup>, the majority of risk reduction occurs at PM<sub>2.5</sub> concentrations between 7 and 9 µg/m<sup>3</sup>. Compared to a lower annual standard level, revising the level of the 24-hour standard to 30 µg/m<sup>3</sup> is estimated to

lower PM<sub>2.5</sub>-associated risks across a more limited range of areas, largely confined to areas located in the western U.S. (several of which are also likely to experience risk reductions upon meeting a revised annual standard).

### **3.4 CASAC ADVICE AND PUBLIC COMMENTS**

As part of its review of the draft PA, the CASAC has provided advice on the adequacy of the public health protection afforded by the current primary PM<sub>2.5</sub> standards. Its advice is documented in a letter sent to the EPA Administrator (Cox, 2019). In this letter, the committee does not reach consensus on whether the scientific and technical information support retaining or revising the current annual PM<sub>2.5</sub> standard.<sup>73</sup> In particular, though the CASAC agrees that there is a long-standing body of health evidence supporting relationships between PM<sub>2.5</sub> exposures and various health outcomes, including mortality and serious morbidity effects, individual CASAC members “differ in their assessments of the causal and policy significance of these associations” (Cox, 2019, p. 8 of consensus responses). Drawing from this evidence, “some CASAC members” express support for retaining the current annual standard while “other members” express support for revising that standard in order to increase public health protection (Cox, 2019, p.1 of letter). These views are summarized below.

The CASAC members who support retaining the current annual standard express the view that substantial uncertainty remains in the evidence for associations between PM<sub>2.5</sub> exposures and mortality or serious morbidity effects. These committee members assert that “such associations can reasonably be explained in light of uncontrolled confounding and other potential sources of error and bias” (Cox, 2019, p. 8 of consensus responses). They note that associations do not necessarily reflect causal effects, and they cite recent reviews (i.e., Henneman et al., 2017; Burns et al., 2019) to support their position that in intervention studies, “reductions of PM<sub>2.5</sub> concentrations have not clearly reduced mortality risks” (Cox, 2019, p. 8 of consensus responses). These members of the CASAC additionally contend that recent epidemiologic studies reporting positive associations at lower estimated exposure concentrations mainly confirm what was anticipated or already assumed in setting the 2012 NAAQS, and that such studies do not provide new information calling into question the existing standard. Thus, they advise that, “while the data on associations should certainly be carefully considered, this data should not be interpreted more strongly than warranted based on its methodological limitations” (Cox, 2019, p. 8 of consensus responses).

---

<sup>73</sup> In contrast, the CASAC reaches the consensus conclusion that the recent scientific evidence does not call into question the adequacy of the 24-hour PM<sub>2.5</sub> standard (Cox 2019, p. 11 of consensus responses).

These members of the CASAC further conclude that the PM<sub>2.5</sub> risk assessment does not provide a valid basis for revising the current standards. This conclusion is based on concerns that 1) "the risk assessment treats regression coefficients as causal coefficients with no justification or validation provided for this decision;" 2) the estimated regression concentration-response functions "have not been adequately adjusted to correct for confounding, errors in exposure estimates and other covariates, model uncertainty, and heterogeneity in individual biological (causal) [concentration-response] functions;" 3) the estimated concentration-response functions "do not contain quantitative uncertainty bands that reflect model uncertainty or effects of exposure and covariate estimation errors;" and 4) "no regression diagnostics are provided justifying the use of proportional hazards...and other modeling assumptions" (Cox, 2019, p. 9 of consensus responses). These committee members also contend that details regarding the derivation of concentration-response functions, including specification of the beta values and functional forms, are not well-documented, hampering the ability of readers to evaluate these design details. Thus, these members "think that the risk characterization does not provide useful information about whether the current standard is protective" (Cox, 2019, p. 11 of consensus responses).

Drawing from their evaluation of the evidence and the risk assessment, these committee members conclude that "the Draft PM PA does not establish that new scientific evidence and data reasonably call into question the public health protection afforded by the current 2012 PM<sub>2.5</sub> annual standard" (Cox, 2019, p.1 of letter).

In contrast, "[o]ther members of CASAC conclude that the weight of the evidence, particularly reflecting recent epidemiology studies showing positive associations between PM<sub>2.5</sub> and health effects at estimated annual average PM<sub>2.5</sub> concentrations below the current standard, does reasonably call into question the adequacy of the 2012 annual PM<sub>2.5</sub> [standard] to protect public health with an adequate margin of safety" (Cox, 2019, p.1 of letter). The committee members who support this conclusion note that the body of health evidence for PM<sub>2.5</sub> includes not only the repeated demonstration of associations in epidemiologic studies, but also includes support for biological plausibility established by human clinical and animal toxicology studies. They point to recent studies demonstrating that the associations between PM<sub>2.5</sub> and health effects occur in a diversity of locations, in different time periods, with different populations, and using different exposure estimation and statistical methods. They conclude that "the entire body of evidence for PM health effects justifies the causality determinations made in the Draft PM ISA" (Cox, 2019, p. 8 of consensus responses).

The members of the CASAC who support revising the current annual standard particularly emphasize recent findings of associations with PM<sub>2.5</sub> in areas with average long-term PM<sub>2.5</sub> concentrations below the level of the annual standard and studies that show positive associations even when estimated exposures above 12 µg/m<sup>3</sup> are excluded from analyses. They

find it “highly unlikely” that the extensive body of evidence indicating positive associations at low estimated exposures could be fully explained by confounding or by other non-causal explanations (Cox, 2019, p. 8 of consensus responses). They additionally conclude that “the risk characterization does provide a useful attempt to understand the potential impacts of alternate standards on public health risks” (Cox, 2019, p. 11 of consensus responses). These committee members conclude that the evidence available in this review reasonably calls into question the protection provided by the current primary PM<sub>2.5</sub> standards and supports revising the annual standard to increase that protection (Cox, 2019).

We also received a number of public comments on the adequacy of the current primary PM<sub>2.5</sub> standards. Some of these commenters, including several representing industry groups and states, agree with the CASAC members who conclude that the evidence supports retaining the current standards. These public commenters often cite the same types of uncertainties that are highlighted by members of the CASAC who support retaining (e.g., potential for confounding, exposure error, etc.). Other public commenters, including those representing environmental and public health organizations and several members of the academic research community, conclude that the current primary PM<sub>2.5</sub> standards should be revised in order to increase public health protection. These commenters generally cite the large body of evidence supporting relationships between PM<sub>2.5</sub> exposures and mortality or serious morbidity-related outcomes, including studies reporting such outcomes for PM<sub>2.5</sub> air quality likely to be allowed in locations meeting the current standards. They conclude that the existing body of epidemiologic studies appropriately considers potential confounders and sources of error, and that this evidence provides robust support for revising the current standards.

### **3.5 CONCLUSIONS ON THE PRIMARY PM<sub>2.5</sub> STANDARDS**

This section describes our conclusions regarding the adequacy of the current primary PM<sub>2.5</sub> standards (section 3.5.1) and regarding potential alternatives for consideration (section 3.5.2). As described more fully in section 3.1.2, our approach to reaching conclusions is based on considering the EPA’s assessment of the current scientific evidence for health effects attributable to PM<sub>2.5</sub> exposures (discussed in detail in the ISA; U.S. EPA, 2019), quantitative assessments of PM<sub>2.5</sub>-associated health risks, and analyses of PM<sub>2.5</sub> air quality. We also consider the range of advice received from the CASAC (Cox, 2019) and comments from the members of the public. These considerations and conclusions are intended to inform the Administrator’s judgments regarding primary standards for fine particles that are requisite to protect public health with an adequate margin of safety. We seek to provide as broad an array of policy options as is supportable by the available science, recognizing that the selection of a specific approach to

reaching final decisions on the primary PM<sub>2.5</sub> standards will reflect the judgments of the Administrator as to what weight to place on the various types of information.

### 3.5.1 Current Standards

We initially consider the adequacy of the current primary PM<sub>2.5</sub> standards. As discussed more fully in section 3.1.2, our approach recognizes that the current annual standard (based on arithmetic mean concentrations) and 24-hour standard (based on 98<sup>th</sup> percentile concentrations), together, are intended to protect the public health against the full distribution of short- and long-term PM<sub>2.5</sub> exposures. In considering the combined effects of these standards, we recognize that changes in PM<sub>2.5</sub> air quality designed to meet an annual standard would likely result not only in lower short- and long-term PM<sub>2.5</sub> concentrations near the middle of the air quality distribution, but also in fewer and lower short-term peak PM<sub>2.5</sub> concentrations. Additionally, changes designed to meet a 24-hour standard, with a 98<sup>th</sup> percentile form, would result not only in fewer and lower peak 24-hour PM<sub>2.5</sub> concentrations, but also in lower annual average PM<sub>2.5</sub> concentrations. Thus, our focus in evaluating the current primary standards is on the protection provided by the combination of the annual and 24-hour standards against the distribution of both short- and long-term PM<sub>2.5</sub> exposures.

Our consideration of the adequacy of the current annual and 24-hour PM<sub>2.5</sub> standards is framed by the first overarching policy-relevant question posed at the beginning of this chapter:

- **Does the currently available scientific evidence and risk-based information support or call into question the adequacy of the public health protection afforded by the current annual and 24-hour PM<sub>2.5</sub> standards?**

In answering this question, we consider the nature of the health effects reported to occur following short- or long-term PM<sub>2.5</sub> exposures, the strength of the evidence supporting those effects, and the evidence that certain populations may be at increased risk (discussed in more detail in sections 3.2.1 and 3.2.2); the PM<sub>2.5</sub> exposures shown to cause effects and the ambient concentrations in locations where PM<sub>2.5</sub> health effect associations have been reported (section 3.2.3); estimates of PM<sub>2.5</sub>-associated health risks for air quality adjusted to simulate just meeting the current annual and 24-hour primary PM<sub>2.5</sub> standards (section 3.3); and advice from the CASAC, based on its review of the draft PA (Cox, 2019). These considerations, and our conclusions on the current primary PM<sub>2.5</sub> standards, are summarized below.

As an initial matter, we note the longstanding body of health evidence supporting relationships between PM<sub>2.5</sub> exposures (short- and long-term) and mortality or serious morbidity effects. The evidence available in this review (i.e., assessed in U.S. EPA, 2019 and summarized above in section 3.2.1) reaffirms, and in some cases strengthens, the conclusions from the 2009 ISA regarding the health effects of PM<sub>2.5</sub> exposures (U.S. EPA, 2009). Much of this evidence

comes from epidemiologic studies conducted in North America, Europe, or Asia that demonstrate generally positive, and often statistically significant, PM<sub>2.5</sub> health effect associations. Such studies report associations between estimated PM<sub>2.5</sub> exposures and non-accidental, cardiovascular, or respiratory mortality; cardiovascular or respiratory hospitalizations or emergency room visits; and other mortality/morbidity outcomes (e.g., lung cancer mortality or incidence, asthma development). Recent experimental evidence, as well as evidence from panel studies, strengthens support for potential biological pathways through which PM<sub>2.5</sub> exposures could lead to the serious effects reported in many population-level epidemiologic studies. This includes support for pathways that could lead to cardiovascular, respiratory, nervous system, and cancer-related effects.

Epidemiologic studies report PM<sub>2.5</sub> health effect associations with mortality and/or morbidity across multiple U.S. cities and in diverse populations, including in studies examining populations and lifestages that may be at comparatively higher risk of experiencing a PM<sub>2.5</sub>-related health effect (e.g., older adults, children). Such studies employ various designs and examine a variety of health outcomes, geographic areas, and approaches to controlling for confounding variables. With regard to controlling for potential confounders in particular, key studies use a wide array of approaches. Time-series studies control for potential confounders that vary over short time intervals (e.g., including temperature, humidity, dew point temperature, and day of the week) while cohort studies control for community- and/or individual-level confounders that vary spatially (e.g., including income, race, age, socioeconomic status, smoking, body mass index, and annual weather variables such as temperature and humidity) (Appendix B, Table B-12). Sensitivity analyses indicate that adding covariates to control for potential confounders can either increase or decrease the magnitude of PM<sub>2.5</sub> effect estimates, depending on the covariate, and that none of the covariates examined can fully explain the association with mortality (e.g., Di et al., 2017b, Figure S2 in Supplementary Materials). Thus, while no individual study adjusts for all potential confounders, a broad range of approaches have been adopted across studies to examine confounding, supporting the robustness of reported associations.

Available studies additionally indicate that PM<sub>2.5</sub> health effect associations are robust across various approaches to estimating PM<sub>2.5</sub> exposures and across exposure windows. This includes recent studies that estimate exposures using ground-based monitors alone and studies that estimate exposures using data from multiple sources (e.g., satellites, land use information, modeling), in addition to monitors. While none of these approaches eliminates the potential for exposure error in epidemiologic studies, such error does not call into question the fundamental findings of the broad body of PM<sub>2.5</sub> epidemiologic evidence. In fact, the ISA notes that while bias in either direction can occur, exposure error tends to lead to underestimation of health

effects in epidemiologic studies of PM exposure (U.S. EPA, 2019, section 3.5). Consistent with this, a recent study reports that correction for PM<sub>2.5</sub> exposure error using personal exposure information results in a moderately larger effect estimate for long-term PM<sub>2.5</sub> exposure and mortality (Hart et al., 2015). While most PM<sub>2.5</sub> epidemiologic studies have not employed similar corrections for exposure error, several studies report that restricting analyses to populations in close proximity to a monitor (i.e., in order to reduce exposure error) result in larger PM<sub>2.5</sub> effect estimates (e.g., Willis et al., 2003; Kloog et al., 2013). The consistent reporting of PM<sub>2.5</sub> health effect associations across exposure estimation approaches, even in the face of exposure error, together with the larger effect estimates reported in some studies that have attempted to reduce exposure error, provides further support for the robustness of associations between PM<sub>2.5</sub> exposures and mortality and morbidity.

Consistent findings from the broad body of epidemiologic studies are also supported by an emerging body of studies employing “causal inference” or quasi-experimental statistical approaches to further inform the causal nature of the relationship between long- or short-term term PM<sub>2.5</sub> exposure and mortality (U.S. EPA, 2019, sections 11.1.2.1, 11.2.2.4). These studies are summarized above in section 3.2.1.1, including a recent accountability study that reports a reduction in mortality following reductions in ambient PM<sub>2.5</sub> due to the introduction of diesel emission controls (Yorifuji et al., 2016).<sup>74</sup> Other recent studies additionally report that declines in ambient PM<sub>2.5</sub> concentrations over a period of years have been associated with decreases in mortality rates and increases in life expectancy, improvements in respiratory development, and decreased incidence of respiratory disease in children, further supporting the robustness of PM<sub>2.5</sub> health effect associations reported in the epidemiologic evidence (summarized in sections 3.2.1 to 3.2.3).

In addition to broadening our understanding of the health effects that can result from exposures to PM<sub>2.5</sub> and strengthening support for some key effects (e.g., nervous system effects, cancer), recent epidemiologic studies strengthen support for health effect associations at relatively low ambient PM<sub>2.5</sub> concentrations. Studies that examine the shapes of concentration-response functions over the full distribution of ambient PM<sub>2.5</sub> concentrations have not identified a threshold concentration, below which associations no longer exist (U.S. EPA, 2019, section 1.5.3). While such analyses are complicated by the relatively sparse data available at the lower

---

<sup>74</sup> Air pollution accountability studies have reported mixed results overall (e.g., as reviewed in Burns et al., 2019 and Henneman et al., 2017). However, many of the available studies have not focused on PM<sub>2.5</sub>, were not able to attribute changes in ambient PM<sub>2.5</sub> concentrations to the interventions under evaluation, and/or were not able to disentangle health impacts of the intervention from background trends in health. The study by Yorifuji et al. (2016), included in the review by Burns et al. (2019), is an example of a study that was able to link a particular policy intervention to a decline in ambient PM<sub>2.5</sub> concentrations, and that did include a control population to correct for background trends in mortality.

end of the air quality distribution (U.S. EPA, 2019, section 1.5.3), several studies report positive and statistically significant associations in additional analyses restricted to annual average PM<sub>2.5</sub> exposures below 12 µg/m<sup>3</sup> (Lee et al., 2015; Di et al., 2017b) and 10 µg/m<sup>3</sup> (Shi et al., 2016), or to daily exposures below 25 µg/m<sup>3</sup> (Di et al., 2017a), 30 µg/m<sup>3</sup> (Shi et al., 2016), and 35 µg/m<sup>3</sup> (Lee et al., 2015).

These and other recent studies provide support for health effect associations at lower ambient PM<sub>2.5</sub> concentrations than in previous reviews. For example, in the last review key epidemiologic studies that were conducted in the U.S. or Canada, and that supported “causal” or “likely to be causal” determinations in the ISA, reported generally positive and statistically significant associations with mortality or morbidity for PM<sub>2.5</sub> air quality distributions with overall mean concentrations at or above 12.8 µg/m<sup>3</sup> (U.S. EPA, 2011, Figure 2-8). In the current review, a large number of key studies report positive and statistically significant associations for air quality distributions with lower overall mean PM<sub>2.5</sub> concentrations (i.e., Figure 3-7 and Figure 3-8). These key studies indicate such associations consistently for distributions with long-term mean PM<sub>2.5</sub> concentrations at or above 8.1 µg/m<sup>3</sup> (8.2 µg/m<sup>3</sup> based on studies that use monitors alone to estimate PM<sub>2.5</sub> exposures), with the large majority (and all but one key U.S. study) reporting overall mean PM<sub>2.5</sub> concentrations at or above 9.6 µg/m<sup>3</sup> (10.7 µg/m<sup>3</sup> based on studies that use monitors alone). Air quality distributions with such low mean concentrations are likely to be allowed by the current PM<sub>2.5</sub> standards, based on analyses of the relationships between maximum annual PM<sub>2.5</sub> design values and annual average concentrations (i.e., averaged across multiple monitors in the same area) (section 3.2.3.2.1; Appendix B, section B.7).<sup>75</sup>

In assessing the adequacy of the current standard, we also consider what key epidemiologic studies may indicate for the current standards by calculating values similar to PM<sub>2.5</sub> design values, based on monitored air quality from the locations and time periods evaluated by those studies (i.e., section 3.2.3.2.2). This approach identifies study-relevant PM<sub>2.5</sub> air quality metrics similar to those used by the EPA to determine whether areas meet or violate the PM NAAQS. Compared to study-reported mean PM<sub>2.5</sub> concentrations, such “pseudo-design values” also have the advantage of being consistently calculated across key studies, regardless of how the studies themselves estimate PM<sub>2.5</sub> exposures (e.g., averaging across monitors, predictions from hybrid modeling approaches).

For some key studies that report positive and statistically significant PM<sub>2.5</sub> health effect associations, substantial portions of study area populations (e.g., > 50% or 75%) lived in

---

<sup>75</sup> Given that the annual standard is the controlling standard across much of the U.S. (e.g., see section 3.3), the PM<sub>2.5</sub> air quality distributions that occur in most locations meeting the current annual PM<sub>2.5</sub> standard are also likely to meet the current 24-hour standard (i.e., illustrated in Chapter 2, Figure 2-11).

locations with air quality likely to have met both the current annual and 24-hour PM<sub>2.5</sub> standards over study periods (or substantial portions of health events occurred in such areas) (section 3.2.3.2.2). While there is uncertainty in interpreting analyses of PM<sub>2.5</sub> pseudo-design values (e.g., some study locations and time periods would have met the current standards while others would have violated those standards, unmonitored areas are excluded from analyses; section 3.2.3.2.2), the importance of these uncertainties is lessened for studies with the large majority of the study area population in locations with pseudo-design values well-below current standard levels (e.g., Pinault et al., 2016; Shi et al., 2016; Weichenthal et al., 2016c). This uncertainty is also lessened for key studies reporting that positive and statistically significant associations persist in analyses restricted to relatively low annual average PM<sub>2.5</sub> exposure estimates (e.g., below 12 µg/m<sup>3</sup> in Di et al., 2017b; below 10 µg/m<sup>3</sup> in Shi et al., 2016), particularly given that the excluded exposure estimates account for about half of the deaths in the entire cohort.<sup>76</sup> Thus, analyses of PM<sub>2.5</sub> pseudo-design values support the occurrence of positive and statistically significant PM<sub>2.5</sub> health effect associations based largely on air quality likely to have met the current primary standards.

In addition to the evidence, we also consider what the risk assessment indicates with regard to the adequacy of the current primary PM<sub>2.5</sub> standards. The risk assessment estimates that the current primary PM<sub>2.5</sub> standards could allow a substantial number of deaths in the U.S., with the large majority of those deaths associated with long-term PM<sub>2.5</sub> exposures. For example, when air quality in the 47 study areas is adjusted to simulate just meeting the current standards, the risk assessment estimates from about 16,000 to 17,000 PM<sub>2.5</sub>-related deaths from ischemic heart disease in a single year (i.e., for long-term exposures; confidence intervals range from about 12,000 to 21,000 deaths). While the absolute numbers of estimated PM<sub>2.5</sub>-associated deaths vary widely across exposure durations, endpoints, populations, and concentration-response functions, the general magnitude of risk estimates supports the potential for significant public health impacts in locations meeting the current primary PM<sub>2.5</sub> standards. This is particularly the case given that the large majority of PM<sub>2.5</sub>-associated deaths for air quality just meeting the current standards are estimated at annual average PM<sub>2.5</sub> concentrations from about 10 to 12 µg/m<sup>3</sup>. These annual average PM<sub>2.5</sub> concentrations fall well-within the range of long-term average concentrations over which key epidemiologic studies provide strong support for reported positive and statistically significant PM<sub>2.5</sub> health effect associations.

Based on the information summarized above, and discussed in more detail in sections 3.2 and 3.3 of this PA, we particularly note the following in reaching conclusions on the current primary PM<sub>2.5</sub> standards:

---

<sup>76</sup> PM<sub>2.5</sub> effect estimates in these restricted analyses are slightly larger than in those based on the entire cohort.

- There is a long-standing body of strong health evidence demonstrating relationships between long- or short-term PM<sub>2.5</sub> exposures and a variety of outcomes, including mortality and serious morbidity effects. Studies published since the last review have reduced key uncertainties and broadened our understanding of the health effects that can result from exposures to PM<sub>2.5</sub>.
- Recent U.S. and Canadian epidemiologic studies provide support for generally positive and statistically significant health effect associations across a broad range of ambient PM<sub>2.5</sub> concentrations, including for air quality distributions with overall mean concentrations lower than in the last review and for distributions likely to be allowed by the current primary PM<sub>2.5</sub> standards.
- Analyses of PM<sub>2.5</sub> pseudo-design values additionally support the occurrence of positive and statistically significant health effect associations based largely on air quality likely to have met the current annual and 24-hour primary standards.
- The risk assessment estimates that the current primary PM<sub>2.5</sub> standards could allow a substantial number of PM<sub>2.5</sub>-associated deaths in the U.S. The large majority of these estimated deaths are associated with the annual average PM<sub>2.5</sub> concentrations near (and above in some cases) the average concentrations in key epidemiologic studies reporting positive and statistically significant health effect associations.

When taken together, we reach the conclusion that the available scientific evidence, air quality analyses, and the risk assessment, as summarized above, can reasonably be viewed as calling into question the adequacy of the public health protection afforded by the combination of the current annual and 24-hour primary PM<sub>2.5</sub> standards.

In contrast to this conclusion, a conclusion that the current primary PM<sub>2.5</sub> standards do provide adequate public health protection would place little weight on the broad body of epidemiologic evidence reporting generally positive and statistically significant health effect associations, particularly for PM<sub>2.5</sub> air quality distributions likely to have been allowed by the current primary standards, or on the PM<sub>2.5</sub> risk assessment. Rather, such a conclusion would place greater weight on uncertainties and limitations in the evidence and analyses (i.e., discussed in sections 3.2.3 and 3.3.2 above), including the following:

- Uncertainty in the biological pathways through which PM<sub>2.5</sub> exposures could cause serious health effects increases as the ambient concentrations being considered fall farther below the PM<sub>2.5</sub> exposure concentrations shown to cause effects in experimental studies. In the current review, such studies generally examine the occurrence of PM<sub>2.5</sub>-attributable effects following exposures to PM<sub>2.5</sub> concentrations well-above those likely to occur in the ambient air in areas meeting the current primary PM<sub>2.5</sub> standards (i.e., discussed in section 3.2.3.1).
- Uncertainty in the potential public health impacts of air quality improvements increases as the ambient concentrations being considered fall farther below those present in studies that report improved health with reductions in PM<sub>2.5</sub> concentrations. In the current review, such

studies evaluate air quality improvements with “starting” mean PM<sub>2.5</sub> concentrations (i.e., prior to the reductions being evaluated) from about 13 to > 20 µg/m<sup>3</sup> (i.e., Table 3-3).<sup>77</sup>

- Uncertainty in the risk assessment results from uncertainties in the underlying epidemiologic studies, in the air quality adjustments, and in the application of study and air quality information to develop quantitative estimates of PM<sub>2.5</sub>-associated mortality risks (section 3.3.2.4).

The considerations and conclusions discussed above are intended to inform the Administrator’s judgments regarding the current primary PM<sub>2.5</sub> standards. In presenting these considerations and conclusions, we seek to provide information on a range of policy options, and on the potential approaches to viewing the scientific evidence and technical information that could potentially support various options. We recognize that the selection of a particular approach to reaching final decisions on the primary PM<sub>2.5</sub> standards will reflect the judgments of the Administrator as to what weight to place on the various types of evidence and information, including associated uncertainties. Given that this PA seeks to provide information on the range of policy options that could be supported by the scientific information, and given our conclusion (noted above) that the evidence and information can reasonably be viewed as calling into question the adequacy of the current primary PM<sub>2.5</sub> standards, in the next section we additionally consider support for potential alternative standards.

### 3.5.2 Potential Alternative Standards

In this section, we consider the potential alternative primary PM<sub>2.5</sub> standards that could be supported by the evidence and quantitative information available in this review. These considerations are framed by the following overarching policy-relevant question, posed at the beginning of this chapter:

- **What is the range of potential alternative standards that could be supported by the available scientific evidence and risk-based information to increase public health protection against short- and long-term fine particle exposures?**

In answering this question, we consider each of the elements of the annual and 24-hour PM<sub>2.5</sub> standards: indicator, averaging time, form, and level. The sections below discuss our consideration of these elements, and our conclusions that (1) it is appropriate to consider revising the level of the current annual standard, in conjunction with retaining the current indicator, averaging time, and form of that standard, to increase public health protection against fine

---

<sup>77</sup> As noted above, these retrospective studies tend to include data from earlier time periods where ambient PM<sub>2.5</sub> concentrations in the U.S. were considerably higher than they are at present.

particle exposures and (2) depending on the decision made on the annual standard, consideration could be given to either retaining or revising the level of the 24-hour PM<sub>2.5</sub> standard.

### **3.5.2.1 Indicator**

In initially setting standards for fine particles in 1997, the EPA concluded it was appropriate to control fine particles as a group, rather than singling out any particular component or class of fine particles. The Agency noted that community health studies had found significant health effect associations using various indicators of fine particles, and that health effects in a large number of areas had significant mass contributions from differing components or sources of fine particles. In addition, a number of toxicological and controlled human exposure studies had reported health effects following exposures to high concentrations of numerous fine particle components (62 FR 38667, July 18, 1997). In establishing a size-based indicator in 1997 to distinguish fine particles from particles in the coarse mode, the EPA noted that the available epidemiologic studies of fine particles were based largely on PM<sub>2.5</sub> mass. The selection of a 2.5 µm size cut additionally reflected the regulatory importance of defining an indicator that would more completely capture fine particles under all conditions likely to be encountered across the U.S. and the monitoring technology that was generally available (62 FR 38666 to 38668, July 18, 1997).

Since the 1997 review, studies that evaluate fine particle-related health effects continue to provide strong support for such effects using PM<sub>2.5</sub> mass as the metric for fine particle exposures. Subsequent reviews have recognized the strength of this evidence, concluding that it has continued to support a PM<sub>2.5</sub> mass-based indicator for a standard meant to protect against fine particle exposures. In the last review, some studies had additionally examined health effects of exposures to particular sources or components of fine particles, or to the ultrafine fraction of fine particles. Based on limitations in such studies, together with the continued strong support for effects of PM<sub>2.5</sub> exposures, the Agency retained PM<sub>2.5</sub> mass as the indicator for fine particles and did not supplement the PM<sub>2.5</sub> standards with standards based on particle composition or on the ultrafine fraction (78 FR 3123, January 15, 2013).

As in the last review, studies available in the current review continue to provide strong support for health effects following long- and short-term PM<sub>2.5</sub> exposures (U.S. EPA, 2019). While some studies evaluate the health effects of particular sources of fine particles, or of particular fine particle components, evidence from these studies does not identify any one source or component that is a better predictor of health effects than PM<sub>2.5</sub> mass (U.S. EPA, 2019, section 1.5.4). The ISA specifically notes that the results of recent studies confirm and further support the conclusion of the 2009 ISA that many PM<sub>2.5</sub> components and sources are associated with health effects, and the evidence does not indicate that any one source or component is

consistently more strongly related with health effects than PM<sub>2.5</sub> mass (U.S. EPA, 2019, section 1.5.4). In addition, the evidence for health effects following exposures specifically to the ultrafine fraction of fine particles continues to be far more limited than the evidence for PM<sub>2.5</sub> mass as a whole. As discussed in the ISA, the lack of a consistent UFP definition in health studies and across disciplines, together with the variety of approaches to administering and measuring UFP in those studies, contribute to such limitations (U.S. EPA, 2019, section 1.4.3). Thus, for reasons similar to those discussed in the last review (78 FR 3121 to 3123, January 15, 2013), we conclude that the available information continues to support the PM<sub>2.5</sub> mass-based indicator and remains too limited to support a distinct standard for any specific PM<sub>2.5</sub> component or group of components, and too limited to support a distinct standard for the ultrafine fraction.

### **3.5.2.2 Averaging Time**

In 1997, the EPA initially set an annual PM<sub>2.5</sub> standard to protect against health effects associated with both long- and short-term PM<sub>2.5</sub> exposures, and a 24-hour standard to supplement the protection afforded by the annual standard (62 FR 38667 to 38668, July 18, 1997). In subsequent reviews, the EPA retained both annual and 24-hour averaging times, largely reflecting the strong evidence for health effects associated with annual and daily PM<sub>2.5</sub> exposure estimates (71 FR 61164, October 17, 2006; 78 FR 3123 to 3124, January 15, 2013).

In the current review, epidemiologic and controlled human exposure studies have examined a variety of PM<sub>2.5</sub> exposure durations. Epidemiologic studies continue to provide strong support for health effects associated with both long- and short-term PM<sub>2.5</sub> exposures based on annual (or multiyear) and 24-hour PM<sub>2.5</sub> averaging periods, respectively.

With regard to short-term exposures in particular, a smaller number of epidemiologic studies examine associations between sub-daily PM<sub>2.5</sub> exposures and respiratory effects, cardiovascular effects, or mortality. Compared to 24-hour PM<sub>2.5</sub> exposure estimates, associations with sub-daily estimates are less consistent and, in some cases, smaller in magnitude (U.S. EPA, 2019, section 1.5.2.1). In addition, studies of sub-daily exposures typically examine subclinical effects, rather than the more serious population-level effects that have been reported to be associated with 24-hour exposures (e.g., mortality, hospitalizations). Taken together, the ISA concludes that epidemiologic studies do not indicate sub-daily averaging periods are more closely associated with health effects than the 24-hour average exposure metric (U.S. EPA, 2019, section 1.5.2.1).

Additionally, while recent controlled human exposure studies provide consistent evidence for cardiovascular effects following PM<sub>2.5</sub> exposures for less than 24 hours (i.e., < 30 minutes to 5 hours), exposure concentrations in these studies are well-above the ambient concentrations typically measured in locations meeting the current standards (section 3.2.3.1). Thus, these

studies also do not suggest the need for additional protection against sub-daily PM<sub>2.5</sub> exposures, beyond that provided by the current primary standards.

Drawing from the evidence assessed in the ISA, and the observations noted above, we reach the conclusion that the available evidence continues to provide strong support for consideration of retaining the current annual and 24-hour averaging times. The available evidence suggests that PM<sub>2.5</sub> standards with these averaging times, when coupled with appropriate forms and levels, can protect against the range of long- and short-term PM<sub>2.5</sub> exposures that have been associated with health effects. Thus, as in the last review, the currently available evidence does not support considering alternatives to the annual and 24-hour averaging times for standards meant to protect against long- and short-term PM<sub>2.5</sub> exposures.

### **3.5.2.3 Form**

The form of a standard defines the air quality statistic that is to be compared to the level in determining whether an area attains that standard. As in other recent reviews, our foremost consideration in reaching conclusions on form is the adequacy of the public health protection provided by the combination of the form and the other elements of the standard.

As noted above, in 1997 the EPA initially set an annual PM<sub>2.5</sub> standard to protect against health effects associated with both long- and short-term PM<sub>2.5</sub> exposures and a 24-hour standard to provide supplemental protection, particularly against the short-term exposures to “peak” PM<sub>2.5</sub> concentrations that can occur in some areas (62 FR 38667 to 38668, July 18, 1997). The EPA established the form of the annual PM<sub>2.5</sub> standard as an annual arithmetic mean, averaged over 3 years, from single or multiple community-oriented monitors. That is, the level of the annual standard was to be compared to measurements made at each community-oriented monitoring site or, if specific criteria were met, measurements from multiple community-oriented monitoring sites could be averaged together (i.e., spatial averaging) (62 FR 38671 to 38672, July 18, 1997). In the 1997 review, the EPA also established the form of the 24-hour PM<sub>2.5</sub> standard as the 98<sup>th</sup> percentile of 24-hour concentrations at each monitor within an area (i.e., no spatial averaging), averaged over three years (62 FR at 38671 to 38674, July 18, 1997). In the 2006 review, the EPA retained these standard forms but tightened the criteria for using spatial averaging with the annual standard (78 FR 3124, January 15, 2013).<sup>78</sup>

In the last review, the EPA’s consideration of the form of the annual PM<sub>2.5</sub> standard again included a focus on the issue of spatial averaging. An analysis of air quality and population demographic information indicated that the highest PM<sub>2.5</sub> concentrations in a given area tended

---

<sup>78</sup> Specifically, the Administrator revised spatial averaging criteria such that “(1) [t]he annual mean concentration at each site shall be within 10 percent of the spatially averaged annual mean, and (2) the daily values for each monitoring site pair shall yield a correlation coefficient of at least 0.9 for each calendar quarter (71 FR 61167, October 17, 2006).

to be measured at monitors in locations where the surrounding populations were more likely to live below the poverty line and to include larger percentages of racial and ethnic minorities (U.S. EPA, 2011, p. 2-60). Based on this analysis, the PA concluded that spatial averaging could result in disproportionate impacts in minority populations and populations with lower SES. The Administrator concluded that public health would not be protected with an adequate margin of safety in all locations, as required by law, if disproportionately higher PM<sub>2.5</sub> concentrations in low income and minority communities were averaged together with lower concentrations measured at other sites in a large urban area. Therefore, she concluded that the form of the annual PM<sub>2.5</sub> standard should be revised to eliminate spatial averaging provisions (78 FR 3124, January 15, 2013).

In the last review, the EPA also considered the form of the 24-hour PM<sub>2.5</sub> standard. The Agency recognized that the existing 98<sup>th</sup> percentile form for the 24-hour standard was originally selected to provide a balance between limiting the occurrence of peak 24-hour PM<sub>2.5</sub> concentrations and identifying a stable target for risk management programs. Updated air quality analyses in the last review provided additional support for the increased stability of the 98<sup>th</sup> percentile PM<sub>2.5</sub> concentration, compared to the 99<sup>th</sup> percentile (U.S. EPA, 2011, Figure 2-2, p. 2-62). Thus, the Administrator concluded that it was appropriate to retain the 98<sup>th</sup> percentile form for the 24-hour PM<sub>2.5</sub> standard (78 FR 3127, January 15, 2013).

Nothing in the evidence that has become available since the last review calls into question the current forms of the annual and 24-hour PM<sub>2.5</sub> standards. As discussed above (section 3.2.3.2), epidemiologic studies continue to provide strong support for health effect associations with both long-term (e.g., annual or multi-year) and short-term (e.g., mostly 24-hour) PM<sub>2.5</sub> exposures. These studies provide the strongest support for such associations for the part of the air quality distribution corresponding to the bulk of the underlying data, typically around the overall mean concentrations reported (section 3.2.3.2.1). The form of the current annual standard (i.e., arithmetic mean, averaged over three years) remains appropriate for targeting protection against the annual and daily PM<sub>2.5</sub> exposures around these means of the PM<sub>2.5</sub> air quality distribution. In addition, controlled human exposure studies provide evidence for health effects following single short-term PM<sub>2.5</sub> exposures near the peak concentrations measured in the ambient air (section 3.2.3.1). Thus, the evidence also supports retaining a standard focused on providing supplemental protection against short-term peak exposures. Nothing in the evidence that has become available since the last review calls into question the decision to use a 98<sup>th</sup> percentile form for a 24-hour standard that is meant to provide a balance between limiting the occurrence of such peak 24-hour PM<sub>2.5</sub> concentrations and identifying a stable target for risk management programs. Thus, when the information summarized above is taken together, we reach the conclusion that it is appropriate in the current review to consider

retaining the forms of the current annual and 24-hour PM<sub>2.5</sub> standards, in conjunction with a revised level as discussed below.

#### 3.5.2.4 Level

With regard to level, we specifically address the following policy-relevant question:

- **For primary PM<sub>2.5</sub> standards defined in terms of the current averaging times and forms, what potential alternative levels are appropriate to consider in order to increase public health protection against long- and short-term exposures to PM<sub>2.5</sub> in ambient air?**

In answering this question, we consider key epidemiologic studies that evaluate associations between PM<sub>2.5</sub> air quality distributions and mortality or morbidity, controlled human exposure studies examining effects following short-term PM<sub>2.5</sub> exposures, air quality analyses that help to place these studies into a policy-relevant context, and the risk assessment estimates of PM<sub>2.5</sub>-associated mortality under various alternative standard scenarios.

As discussed above in section 3.1.2, consideration of the evidence and analyses, as summarized in this chapter, informs our evaluation of the public health protection that could be provided by alternative annual and 24-hour standards with revised levels. There are various ways to combine an annual standard (based on arithmetic mean concentrations) and a 24-hour standard (based on 98<sup>th</sup> percentile concentrations), to achieve an appropriate degree of public health protection. In particular, as noted in section 3.1.2, we recognize that changes in PM<sub>2.5</sub> air quality designed to meet an annual standard would likely result not only in lower short- and long-term PM<sub>2.5</sub> concentrations near the middle of the air quality distribution (i.e., around the mean of the distribution), but also in fewer and lower short-term peak PM<sub>2.5</sub> concentrations. Additionally, changes designed to meet a 24-hour standard, with a 98<sup>th</sup> percentile form, would result not only in fewer and lower peak 24-hour PM<sub>2.5</sub> concentrations, but also in lower average PM<sub>2.5</sub> concentrations.

However, while either standard could be viewed as providing some measure of protection against both average exposures and peak exposures, the 24-hour and annual standards are not expected to be equally effective at limiting both types of exposures. Specifically, the 24-hour standard (with its 98<sup>th</sup> percentile form) is more directly tied to short-term peak PM<sub>2.5</sub> concentrations, and thus more likely to appropriately limit exposures to such concentrations, than to the more typical concentrations that make up the middle portion of the air quality distribution. Therefore, compared to a standard that is directly tied to the middle of the air quality distribution, the 24-hour standard is less likely to appropriately limit the “typical” daily and annual exposures that are most strongly associated with the health effects observed in epidemiologic studies. In contrast, the annual standard, with its form based on the arithmetic mean concentration, is more likely to effectively limit the PM<sub>2.5</sub> concentrations that comprise the middle portion of the air

quality distribution, affording protection against the daily and annual PM<sub>2.5</sub> exposures that strongly support associations with the most serious PM<sub>2.5</sub>-related effects in epidemiologic studies (e.g., mortality, hospitalizations).

For these reasons, as discussed in section 3.1.2, we focus on alternative levels of the annual PM<sub>2.5</sub> standard as the principle means of providing increased public health protection against the bulk of the distribution of short- and long-term PM<sub>2.5</sub> exposures, and thus protecting against the exposures that provide strong support for associations with mortality and morbidity in key epidemiologic studies. We additionally consider the 24-hour standard, with its 98<sup>th</sup> percentile form, primarily as a means of providing supplemental protection against the short-term exposures to peak PM<sub>2.5</sub> concentrations that can occur in some areas (e.g., those with strong contributions from local or seasonal sources), even when overall mean PM<sub>2.5</sub> concentrations remain relatively low.

To inform our consideration of potential alternative annual and 24-hour standard levels, we specifically note the following key observations regarding (1) the overall mean PM<sub>2.5</sub> concentrations reported in U.S. or Canadian epidemiologic studies, (2) the relationships between long-term mean PM<sub>2.5</sub> concentrations and annual design values in U.S. CBSAs, (3) the PM<sub>2.5</sub> pseudo-design values in study locations, (4) the PM<sub>2.5</sub> exposures shown to cause effects in controlled human exposure studies, and (5) estimated PM<sub>2.5</sub>-associated risks.

***(1) Long-Term Mean PM<sub>2.5</sub> Concentrations in Key Epidemiologic Studies (section 3.2.3.2)***

- Key epidemiologic studies indicate consistently positive and statistically significant health effect associations based on air quality distributions with overall long-term mean PM<sub>2.5</sub> concentrations at and above 8.1 µg/m<sup>3</sup> (8.2 µg/m<sup>3</sup> based on studies that use monitors alone to estimate PM<sub>2.5</sub> exposures), with mean concentrations at or above 9.6 µg/m<sup>3</sup> in most key studies (10.7 µg/m<sup>3</sup> based on studies that use monitors alone to estimate PM<sub>2.5</sub> exposures). The ranges of ambient PM<sub>2.5</sub> concentrations accounting for the bulk of exposures and health data in these studies are expected to extend at least somewhat below the overall long-term mean concentrations reported.
- Epidemiologic studies provide more limited support for health effect associations based on air quality distributions with lower overall mean PM<sub>2.5</sub> concentrations. Specifically, two key studies report positive associations between short-term PM<sub>2.5</sub> exposures and emergency room visits based on cities in Ontario, Canada (Weichenthal et al., 2016b and Weichenthal et al., 2016c and), with overall mean PM<sub>2.5</sub> concentrations around 7.0 µg/m<sup>3</sup> (one of these studies reports an association that is statistically significant). Additionally, a U.S. study (Shi et al. (2016) reports positive and statistically significant associations in analyses restricted to relatively low annual or 24-hour PM<sub>2.5</sub> exposure estimates. This study does not report the overall mean PM<sub>2.5</sub> concentrations in restricted analyses, though such means are presumably somewhat below those based on the overall cohort (i.e., 8.1 and 8.2 µg/m<sup>3</sup>).

**(2) *Relationships between long-term mean PM<sub>2.5</sub> concentrations and annual design values (section 3.2.3.3; Appendix B, section B.7)***

- Areas meeting a particular annual PM<sub>2.5</sub> standard would be expected to have average PM<sub>2.5</sub> concentrations (i.e., averaged across the area and over time) somewhat below the level of that standard. This is supported by analyses of monitoring data in CBSAs across the U.S., which show that maximum annual PM<sub>2.5</sub> design values are often 10% to 20% higher than long-term mean PM<sub>2.5</sub> concentrations (Appendix B, Figure B-7; Table B-9).

**(3) *PM<sub>2.5</sub> Pseudo-Design Values in Study Locations (section 3.2.3.2.2 and Appendix B, Figure B-9)***

- For most key epidemiologic studies with PM<sub>2.5</sub> pseudo-design values available, about 25% or more of study area populations lived in locations likely to have met the current primary PM<sub>2.5</sub> standards over study periods (or about 25% or more of health events occurred in such locations). For the U.S. studies in this group, annual pseudo-design values as low as 8.7 µg/m<sup>3</sup> correspond to 25<sup>th</sup> percentiles of study area population (or health events). For the smaller number of Canadian studies included in this group, annual pseudo-design values as low as 6.0 µg/m<sup>3</sup> correspond to the 25<sup>th</sup> percentiles of study area population (or health events).
- For several key epidemiologic studies, most of the study area populations (i.e., >50% of those living in areas with pseudo-design values) lived in locations with air quality likely to have met both standards over study periods (or >50% of health events occurred in locations with such air quality). For the U.S. studies in this group, annual pseudo-design values from 9.9 to 11.7 µg/m<sup>3</sup> correspond to 50<sup>th</sup> percentiles of study area populations (or health events). For the smaller number of Canadian studies included in this group, annual pseudo-design values from 7.3 to 7.4 µg/m<sup>3</sup> correspond to 50<sup>th</sup> percentiles of study area populations (or health events).
- For the U.S. study reporting the lowest annual average concentrations (Shi et al., 2016), an annual pseudo-design value of 11.0 µg/m<sup>3</sup> corresponds to the 75<sup>th</sup> percentile of the study area population (i.e., 75% of the study area population lives in locations with pseudo-design values < 11.0 µg/m<sup>3</sup>). For the Canadian studies with the lowest ambient PM<sub>2.5</sub> concentrations, annual pseudo-design values from 8.4 to 8.6 µg/m<sup>3</sup> correspond to 75<sup>th</sup> percentiles of the study area populations (or health events).

**(4) *PM<sub>2.5</sub> exposures shown to cause effects in controlled human exposure studies (section 3.2.3.1)***

- While controlled human exposure studies support the plausibility of the serious cardiovascular effects that have been linked with ambient PM<sub>2.5</sub> exposures (U.S. EPA, 2019, Chapter 6), the PM<sub>2.5</sub> exposure concentrations evaluated in most of these studies are well-above the ambient concentrations typically measured in locations meeting the current primary standards (and thus well-above those likely to be measured in locations that would meet revised standards with lower annual or 24-hour levels).

**(5) *PM<sub>2.5</sub>-Associated Risk Estimates (section 3.3)***

- The risk assessment estimates that, compared to the current standards, potential alternative annual standards with levels from 11.0 down to 9.0  $\mu\text{g}/\text{m}^3$  could reduce  $\text{PM}_{2.5}$ -associated mortality broadly across the U.S., including in most of the 47 urban study areas evaluated. In such locations, estimated risk reductions range from about 7 to 9% for a level of 11.0  $\mu\text{g}/\text{m}^3$ , 14 to 18% for a level of 10.0  $\mu\text{g}/\text{m}^3$ , and 21 to 27% for a level of 9.0  $\mu\text{g}/\text{m}^3$ . For each of these standards, most of the risk remaining is estimated at annual average  $\text{PM}_{2.5}$  concentrations that fall somewhat below the standard level.
- Risk reductions estimated for an alternative 24-hour standard with a level of 30  $\mu\text{g}/\text{m}^3$  are concentrated in only a few study areas in the western U.S. (several of which could also experience risk reductions in response to a revised annual standard with a level below 12.0  $\mu\text{g}/\text{m}^3$ ). In those few study areas for which risk reductions are estimated upon just meeting an alternative 24-hour standard with a level of 30  $\mu\text{g}/\text{m}^3$ , reductions range from about 14 to 18%.

The information summarized in these key observations could support various decisions on the levels of the annual and 24-hour  $\text{PM}_{2.5}$  standards, depending on the weight given to different aspects of the evidence, air quality and risk information, including its uncertainties. As noted above (section 3.1.2), in this PA we seek to provide as broad an array of policy options as is supportable by the available evidence and quantitative information, recognizing that the selection of a specific approach to reaching final decisions on the primary  $\text{PM}_{2.5}$  standards will reflect the judgments of the Administrator as to what weight to place on the various types of evidence and information, and on associated uncertainties. Potential approaches to considering support for particular alternative annual and 24-hour standard levels are discussed below.

#### **3.5.2.4.1 Alternative Annual Standard Levels**

As discussed above, the degree to which particular alternative annual standard levels below 12.0  $\mu\text{g}/\text{m}^3$  are supported will depend on the weight placed on various aspects of the scientific evidence, air quality and risk information, and its associated uncertainties. For example, a level as low as about 10.0  $\mu\text{g}/\text{m}^3$  could be supported to the extent weight is placed on the following:

- Setting a standard expected to maintain the  $\text{PM}_{2.5}$  air quality distribution below those present in most key epidemiologic studies, recognizing that (1) the large majority of key studies reporting positive and statistically significant health effect associations (and all but one key U.S. study) examine distributions of ambient  $\text{PM}_{2.5}$  with overall mean concentrations at or above 9.6  $\mu\text{g}/\text{m}^3$ , while a few studies reporting such associations examine distributions with overall mean concentrations just above 8.0  $\mu\text{g}/\text{m}^3$  (section 3.2.3.2.1) and (2) analyses of  $\text{PM}_{2.5}$  air quality in CBSAs indicate that maximum annual  $\text{PM}_{2.5}$  design values are often 10% to 20% higher than average  $\text{PM}_{2.5}$  concentrations (i.e., averaged across space and over several years) suggesting that areas meeting a particular annual  $\text{PM}_{2.5}$  standard would be expected to have average  $\text{PM}_{2.5}$  concentrations somewhat below the level of that standard (section 3.2.3.2.2; Appendix B, section B.7);

- Setting the standard level at or below the pseudo-design values corresponding to about the 50<sup>th</sup> percentiles of study area populations (or health events) in most key studies (particularly key U.S. studies), recognizing that a revised annual standard with a level as low as 10.0  $\mu\text{g}/\text{m}^3$  would be expected to maintain ambient  $\text{PM}_{2.5}$  concentrations below the concentrations present during study periods for most of those populations (or below the concentrations in locations accounting for most health events) (section 3.2.3.2.2);
- Setting a standard estimated to reduce  $\text{PM}_{2.5}$ -associated health risks, such that a substantial portion of the risk reduction is estimated at annual average  $\text{PM}_{2.5}$  concentrations  $\geq$  about 8  $\mu\text{g}/\text{m}^3$  and recognizing that these concentrations are within the range of overall means for which key epidemiologic studies indicate consistently positive and statistically significant health effect associations (section 3.3.2).

In selecting a particular level from 10.0  $\mu\text{g}/\text{m}^3$  to < 12.0  $\mu\text{g}/\text{m}^3$ , consideration of the evidence could take into account individual study characteristics such as study design and statistical approaches, precision of reported associations, study size and location, and uncertainties in the study itself or in our analyses of study area air quality. For example, if less weight is placed on the small number of studies reporting overall mean concentrations below 9.6  $\mu\text{g}/\text{m}^3$  and on the small number of studies with 50<sup>th</sup> percentile pseudo-design values below 10.0  $\mu\text{g}/\text{m}^3$ , a standard higher than 10  $\mu\text{g}/\text{m}^3$  (but still below 12.0  $\mu\text{g}/\text{m}^3$ ) might be considered. Similarly, consideration of the risk assessment could take into account the magnitude of estimated risk reductions, compared to the current standards; the annual average  $\text{PM}_{2.5}$  concentrations at which those reductions are estimated to occur; and the uncertainties in the underlying epidemiologic studies, in the air quality adjustments, or in other information that was used to model risks. For example, concern about the uncertainty in the potential public health importance of risk reductions estimated for a level as low as 10.0  $\mu\text{g}/\text{m}^3$ , much of which is estimated at annual average  $\text{PM}_{2.5}$  concentrations around 8  $\mu\text{g}/\text{m}^3$ , might focus consideration on a standard level above 10  $\mu\text{g}/\text{m}^3$ , where estimated risk reductions would occur at slightly higher concentrations.

A decision to not consider annual standard levels below 10.0  $\mu\text{g}/\text{m}^3$  might take into account the increasing uncertainty in the degree to which lower levels would result in additional public health improvements, due in part to the more limited amount of data available. Such a decision could note the following regarding the increasing uncertainty at lower ambient concentrations:

- Few key epidemiologic studies (and only one key U.S. study) report positive and statistically significant health effect associations for  $\text{PM}_{2.5}$  air quality distributions with overall mean concentrations below 9.6  $\mu\text{g}/\text{m}^3$ , and areas meeting a standard with a level of 10.0  $\mu\text{g}/\text{m}^3$  would generally be expected to have lower long-term mean  $\text{PM}_{2.5}$  concentrations (and potentially around 8.0  $\mu\text{g}/\text{m}^3$  in some areas) (section 3.2.3.2.1; Appendix B, section B.7).

- There is increasing uncertainty in PM<sub>2.5</sub> exposure estimates in some of the largest key studies at lower ambient concentrations (i.e., those that use hybrid model predictions to estimate exposures), given the more limited information available to develop and validate model predictions (sections 2.3.3 and 3.2.3.2.1).
- Pseudo-design values corresponding to the 50<sup>th</sup> percentiles of study area populations (or health events) are  $\geq$  about 10.0  $\mu\text{g}/\text{m}^3$  for almost all key studies, particularly those conducted in the U.S. (section 3.2.3.2.2).
- There is increasing uncertainty in quantitative estimates of PM<sub>2.5</sub>-associated mortality risk for standard levels below 10.0  $\mu\text{g}/\text{m}^3$ , given that a substantial proportion of the risk reductions estimated for lower standard levels occur at annual average PM<sub>2.5</sub> concentrations below 8  $\mu\text{g}/\text{m}^3$ , and thus below the lower end of the range of overall mean PM<sub>2.5</sub> concentrations in key epidemiologic studies that consistently report positive and statistically significant associations (section 3.3.2).

In contrast, an annual standard with a level below 10.0  $\mu\text{g}/\text{m}^3$ , and potentially as low as 8.0  $\mu\text{g}/\text{m}^3$ , could be supported to the extent greater weight is placed on the potential public health improvements that could result from additional reductions in ambient PM<sub>2.5</sub> concentrations (i.e., beyond those achieved by a standard with a level of 10.0  $\mu\text{g}/\text{m}^3$ ) and less weight is placed on the limitations in the evidence that contribute to greater uncertainty at lower concentrations. For example, a level below 10.0  $\mu\text{g}/\text{m}^3$  could be supported to the extent greater weight is placed on the following:

- The two key studies in Canada with overall mean PM<sub>2.5</sub> concentrations below 8.0  $\mu\text{g}/\text{m}^3$  and the potential for overall mean concentrations below 8.0  $\mu\text{g}/\text{m}^3$  in restricted analyses in a key U.S. study (section 3.2.3.2.1);
- The ambient PM<sub>2.5</sub> concentrations somewhat below overall means (e.g., corresponding the lower quartile of underlying data), which contribute to the bulk of the data informing reported associations (section 3.2.3.2.1);
- Annual pseudo-design values corresponding to 25<sup>th</sup> percentiles of study area populations or health events for most studies, recognizing that the revised standard would be expected to maintain ambient PM<sub>2.5</sub> concentrations below the concentrations present during study periods for  $> \sim 75\%$  of those populations (or below the concentrations in locations accounting for  $> 75\%$  of health events) (section 3.2.3.2.2);
- Annual pseudo-design values for the smaller number of key studies conducted in Canada, which tend to be somewhat lower than those in the U.S. (section 3.2.3.2.2);
- The potential public health importance of the additional reductions in PM<sub>2.5</sub>-associated health risks estimated for a level of 9.0  $\mu\text{g}/\text{m}^3$  and the potential for continued reductions at lower standard levels (i.e., below the lowest level examined in the risk assessment) (section 3.3).

As above, various levels from 8.0  $\mu\text{g}/\text{m}^3$  to  $< 10.0 \mu\text{g}/\text{m}^3$  could be supported, depending on the weight placed on specific aspects of the evidence and analyses. For example, compared to a level of 8.0  $\mu\text{g}/\text{m}^3$ , a higher level could be supported to the extent less weight is placed on the

two key Canadian studies reporting overall mean concentrations below  $8.0 \mu\text{g}/\text{m}^3$ , on the potential for overall mean concentrations below  $8.0 \mu\text{g}/\text{m}^3$  in a U.S. study that reports associations in restricted analyses, and on the three Canadian studies with the lowest pseudo-design values. Such a judgment could also be informed by increasing uncertainty in the potential public health importance of risks estimated for a level as low as  $8.0 \mu\text{g}/\text{m}^3$ , given that such risks, which were not quantified in the risk assessment, are likely to occur at annual average  $\text{PM}_{2.5}$  concentrations largely below  $8 \mu\text{g}/\text{m}^3$  (i.e., below the mean concentrations in almost all key epidemiologic studies).

#### **3.5.2.4.2 Alternative 24-Hour Standard Levels**

We additionally evaluate the degree to which the evidence supports considering potential alternative levels for the 24-hour  $\text{PM}_{2.5}$  standard, in conjunction with the current 98<sup>th</sup> percentile form of that standard. As discussed above (section 3.1.1), in the last review, the EPA recognized that the annual standard would generally be the controlling standard across much of the U.S., except for certain areas in the western U.S. “where annual mean  $\text{PM}_{2.5}$  concentrations have historically been low but where relatively high 24-hour concentrations occur, often related to seasonal wood smoke emissions” (78 FR 3163, January 15, 2013). In such areas, the 24-hour standard is the generally controlling standard. Thus, the EPA’s approach in the last review was to focus on the annual standard as the principle means of limiting both long- and short-term  $\text{PM}_{2.5}$  concentrations, recognizing that the 24-hour standard, with its 98<sup>th</sup> percentile form, would provide supplemental protection against short-term peak exposures, particularly for areas with high peak-to-mean ratios (e.g., areas with strong seasonal sources).

As discussed above (section 3.1.2), in the current review we again view the 24-hour standard (with its 98<sup>th</sup> percentile form) largely within the context of limiting short-term exposures to peak  $\text{PM}_{2.5}$  concentrations. Compared to the annual standard, we recognize that the 24-hour standard is less likely to appropriately limit the more typical  $\text{PM}_{2.5}$  exposures (i.e., corresponding to the middle portion of the air quality distribution) that are most strongly associated with the health effects observed in epidemiologic studies. Thus, as in the last review (78 FR 3161-3162, January 15, 2013), we focus on the annual  $\text{PM}_{2.5}$  standard as the principle means of providing public health protection against the bulk of the distribution of short- and long-term  $\text{PM}_{2.5}$  exposures, and the 24-hour standard as a means of providing supplemental protection against the short-term exposures to “peak”  $\text{PM}_{2.5}$  concentrations, such as can occur in areas with strong contributions from local or seasonal sources.

Results of the risk assessment and of recent air quality analyses are consistent with our reliance on the 24-hour standard to provide supplemental protection in areas with relatively low long-term mean  $\text{PM}_{2.5}$  concentrations. In particular, the risk assessment indicates that the annual

standard is the controlling standard across most of the urban study areas evaluated and revising the level of the 24-hour standard to  $30 \mu\text{g}/\text{m}^3$  would be estimated to lower  $\text{PM}_{2.5}$ -associated risks, compared to the current standards, largely in a few study areas located in the western U.S. (several of which are also likely to experience risk reductions upon meeting a revised annual standard). Additionally, recent air quality analyses indicate that almost all CBSAs with maximum annual  $\text{PM}_{2.5}$  design values at or below  $12.0 \mu\text{g}/\text{m}^3$  also have maximum 24-hour design values below  $35 \mu\text{g}/\text{m}^3$  (and below  $30 \mu\text{g}/\text{m}^3$  in most areas) (Chapter 2, Figure 2-11). The exceptions are a few CBSAs in the western U.S.

Thus, taking into account the approach described above, an important consideration is whether additional protection is needed against short-term exposures to peak  $\text{PM}_{2.5}$  concentrations in areas meeting both the current 24-hour standard and the current, or a revised, annual standard. To the extent the evidence indicates that such exposures can lead to adverse health effects, it would be appropriate to consider alternative levels for the 24-hour standard. In considering this issue, we evaluate the evidence from key health studies. With regard to these studies, we particularly note the following:

- To the extent a revised annual standard is determined to provide adequate protection against the 24-hour and annual  $\text{PM}_{2.5}$  exposures associated with health effects in key epidemiologic studies, those studies do not indicate the need for additional protection against short-term exposures to peak  $\text{PM}_{2.5}$  concentrations. As discussed in detail above (section 3.2.3.2.1), epidemiologic studies provide the strongest support for reported health effect associations for the part of the air quality distribution corresponding to the bulk of the underlying data (i.e., estimated exposures and/or health events), often around the overall mean concentrations evaluated rather than near the upper end of the distribution. Consistent with this, analyses that exclude the upper end of the distribution of estimated exposures still find positive and statistically significant associations with mortality. The magnitudes of the associations in restricted analyses are similar to (Shi et al., 2016) or larger than (Di et al., 2017a) the magnitudes of the associations based on the full cohorts, suggesting that, at a minimum, short-term exposures to peak  $\text{PM}_{2.5}$  concentrations are not disproportionately responsible for reported health effect associations.
- Controlled human exposure studies do provide evidence for health effects following single, short-term  $\text{PM}_{2.5}$  exposures to concentrations that typically correspond to upper end of the  $\text{PM}_{2.5}$  air quality distribution in the U.S. (i.e., “peak” concentrations). However, most of these studies examine exposure concentrations considerably higher than are typically measured in areas meeting the current standards (section 3.2.3.1). In particular, while controlled human exposure studies often report statistically significant effects on one or more indicators of cardiovascular function following 2-hour exposures to  $\text{PM}_{2.5}$  concentrations at and above  $120 \mu\text{g}/\text{m}^3$  (at and above  $149 \mu\text{g}/\text{m}^3$  for vascular impairment, the effect shown to be most consistent across studies), 2-hour ambient concentrations of  $\text{PM}_{2.5}$  at monitoring sites meeting the current standards almost never exceed  $32 \mu\text{g}/\text{m}^3$ . In fact, even the extreme upper end of the distribution of 2-hour  $\text{PM}_{2.5}$  concentrations at sites meeting the current standards remains well-below the  $\text{PM}_{2.5}$  exposure concentrations consistently shown to elicit effects

(i.e., 99.9<sup>th</sup> percentile of 2-hour concentrations at these sites is 68  $\mu\text{g}/\text{m}^3$  during the warm season). Thus, available  $\text{PM}_{2.5}$  controlled human exposure studies do not indicate the need for additional protection against exposures to peak  $\text{PM}_{2.5}$  concentrations, beyond the protection provided by the combination of the current 24-hour standard and the current or a revised annual standard (section 3.2.3.1).

When the information summarized above is considered in the context of the 24-hour standard, we reach the conclusion that, in conjunction with a lower annual standard level intended to increase protection against short- and long-term  $\text{PM}_{2.5}$  exposures broadly across the U.S., the evidence does not support the need for additional protection against short-term exposures to peak  $\text{PM}_{2.5}$  concentrations. In particular, while epidemiologic studies do support the need to consider increasing protection against the typical 24-hour and annual  $\text{PM}_{2.5}$  exposures that provide strong support for reported health effect associations, these studies do not indicate that such associations are strongly influenced by exposures to the peak concentrations in the air quality distribution. Also, while controlled human exposure studies support the occurrence of effects following single short-term exposures to  $\text{PM}_{2.5}$  concentrations that correspond to the peak of the air quality distribution, these concentrations are well above those typically measured in areas meeting the current standards. Thus, in the context of a 24-hour standard that is meant to provide supplemental protection (i.e., beyond that provided by the annual standard alone) against short-term exposures to peak  $\text{PM}_{2.5}$  concentrations, the available evidence supports consideration of retaining the current 24-hour standard with its level of 35  $\mu\text{g}/\text{m}^3$ .

However, we also recognize that a different policy approach than that described above could be applied to considering the level of the 24-hour standard. For example, consideration could be given to lower 24-hour standard levels in order to increase protection across the U.S. against the broader  $\text{PM}_{2.5}$  air quality distribution. If such an approach is evaluated in the current review, consideration of 24-hour standard levels at least as low as 30  $\mu\text{g}/\text{m}^3$  could be supported (either alone or in conjunction with a lower annual standard level). The risk assessment estimates that a level of 30  $\mu\text{g}/\text{m}^3$  would increase protection compared to the current standards, though only in a small number of study areas largely confined to the western U.S. (section 3.3.2). Analyses of air quality in locations of some key epidemiologic studies indicate that substantial portions of study area populations lived in locations with 24-hour  $\text{PM}_{2.5}$  pseudo-design values at or below about 30  $\mu\text{g}/\text{m}^3$  (or that substantial portions of study health events occurred in such locations), providing additional support for considering lower levels.

If this alternative approach to revising the primary  $\text{PM}_{2.5}$  standards is adopted, the uncertainty inherent in using the 24-hour standard to increase protection against the broad distribution of  $\text{PM}_{2.5}$  air quality should be carefully considered. Specifically, the degree of

protection provided by any particular 24-hour standard against the typical short- and long-term PM<sub>2.5</sub> exposures corresponding to the middle portion of the air quality distribution will vary across locations and over time, depending on the relationship between those typical concentrations and the short-term peak PM<sub>2.5</sub> concentrations that are directly targeted by the 24-hour standard (i.e., with its 98<sup>th</sup> percentile form). Thus, lowering the level of the 24-hour standard is likely to have a more variable impact on public health than lowering the level of the annual standard. Depending on the 24-hour standard level set, some areas could experience reductions that are greater than warranted, based on the evidence, while others could experience reductions that are less than warranted. Therefore, the rationale supporting this approach would need to recognize and account for the uncertainty inherent in using 24-hour standard, with a 98<sup>th</sup> percentile form, to increase protection against the broad distribution of PM<sub>2.5</sub> air quality.

### **3.6 AREAS FOR FUTURE RESEARCH AND DATA COLLECTION**

In this section, we identify key areas for additional research and data collection for fine particles, based on the uncertainties and limitations that remain in the evidence and technical information. Additional research in these areas could reduce uncertainties and limitations in future reviews of the primary PM<sub>2.5</sub> standards. Important areas for future research include the following:

- Further elucidating the physiological pathways through which exposures to the PM<sub>2.5</sub> concentrations present in the ambient air across much of the U.S. could be causing mortality and the morbidity effects shown in many epidemiologic studies. This could include the following:
  - Controlled human exposure studies that examine longer exposure periods (e.g., 24-hour as in Bräuner et al. (2008); 5-hour as in Hemmingsen et al. (2015b)), or repeated exposures, to concentrations typically measured in the ambient air across the U.S.
  - Studies that evaluate the health impacts of decreasing PM<sub>2.5</sub> exposures (e.g., due to changes in policies or behavior, shifts in important emissions sources, or targeted interventions).
  - Additional animal toxicological studies that evaluate exposures to low PM<sub>2.5</sub> concentrations.
- Additional research into “causal inference” methods in epidemiologic studies to evaluate the causal nature of relationships between PM<sub>2.5</sub> exposure and mortality or morbidity.
- Improving our understanding of the PM<sub>2.5</sub> concentration-response relationships near the lower end of the PM<sub>2.5</sub> air quality distribution, including the shapes of concentration-response functions and the uncertainties around estimated functions for various health outcomes and populations (e.g., older adults, people with pre-existing diseases, children).

- Understanding of the potential for particle characteristics, other than size-fractionated mass, to influence PM toxicity (e.g., composition, oxidative potential, etc.) and the PM health effect associations observed in epidemiologic studies.
- Improving our understanding of the uncertainties inherent in the various approaches used to estimate PM<sub>2.5</sub> exposures in epidemiologic studies, including how those uncertainties may vary across space and time, and over the PM<sub>2.5</sub> air quality distribution. Approaches to incorporating these uncertainties into quantitative estimates of PM<sub>2.5</sub> concentration-response relationships should also be explored.
- Additional health research on ultrafine particles, with a focus on consistently defining UFPs across studies and across disciplines (i.e., animal, controlled human exposure, and epidemiologic studies), on using consistent exposure approaches in experimental studies, and on improving exposure characterizations in epidemiologic studies. Also, further examine the potential for translocation of ultrafine particles from the respiratory tract into other compartments (i.e., blood) and organs (e.g., heart, brain), with particular emphasis on studies conducted in humans.
- Additional work to measure ultrafine particle emissions, using comparable methods to measure emissions from various types of sources (e.g., mobile sources, fires, etc.).
- Further evaluate the potential for some groups to be at higher risk of PM<sub>2.5</sub>-related effects than the general population and the potential for PM<sub>2.5</sub> exposures to contribute to the development of underlying conditions that may then confer higher risk of PM<sub>2.5</sub>-related effects. For example, research to address this latter need could include efforts to understand the potential for long-term PM exposures to contribute to the development and progression of atherosclerosis in adults and/or asthma in children. It could also include research to understand the potential role of PM exposures in developmental outcomes (e.g., neurodevelopmental effects, reproductive and birth outcomes).
- Research to further evaluate the combination of factors that contribute to differences in risk estimates between cities, potentially including differences in exposures, demographics, particle characteristics.
- Research to improve our understanding of variability in PM<sub>2.5</sub> exposures within and across various populations (e.g., defined by life stage, pre-existing condition, etc.), the most health-relevant exposure durations, as well as the temporal and spatial variability in ambient PM<sub>2.5</sub> that is not captured by existing ambient monitors.

## 4 REVIEW OF THE PRIMARY STANDARD FOR PM<sub>10</sub>

This chapter presents key policy-relevant considerations and conclusions regarding the public health protection provided by the current primary PM<sub>10</sub> standard. These considerations and conclusions are framed by a series of policy-relevant questions, including the following overarching policy-relevant question:

- **Does the currently available scientific evidence support or call into question the adequacy of the protection afforded by the current 24-hour primary PM<sub>10</sub> standard against health effects associated with exposures to PM<sub>10-2.5</sub>?**

The answer to this question is intended to inform decisions by the Administrator on whether, and if so, how to revise the primary standard for PM<sub>10</sub>.

Section 4.1 summarizes the EPA's approach to reviewing the primary PM<sub>10</sub> standard in the last review and our general approach to considering the updated scientific evidence in the current review. Section 4.2 presents our consideration of the available evidence as assessed in the ISA. Section 4.3 summarizes CASAC advice and public comments. Drawing from that consideration of the evidence, section 4.4 summarizes our conclusions regarding the adequacy of the current primary PM<sub>10</sub> standard. Section 4.5 discusses areas for future research and data collection to improve our understanding of potential PM<sub>10-2.5</sub>-related health effects in future reviews.

### 4.1 APPROACH

#### 4.1.1 Approach Used in the Last review

The last review of the PM NAAQS was completed in 2012 (78 FR 3086, January 15, 2013). In that review the EPA retained the existing 24-hour primary PM<sub>10</sub> standard, with its level of 150 µg/m<sup>3</sup> and its one-expected-exceedance form on average over three years, to continue to provide public health protection against exposures to PM<sub>10-2.5</sub>. In support of this decision, the Administrator emphasized her consideration of three issues: the extent to which it was appropriate to maintain a standard that provides some measure of protection against all PM<sub>10-2.5</sub> (regardless of composition or source or origin), the extent to which a standard with a PM<sub>10</sub> indicator can provide protection against exposures to PM<sub>10-2.5</sub>, and the degree of public health protection provided by the existing PM<sub>10</sub> standard. Her consideration of each of these issues is summarized below.

First, the Administrator judged that the evidence provided “ample support for a standard that protects against exposures to all thoracic coarse particles, regardless of their location or source of origin” (78 FR 3176, January 15, 2013). In support of this, she noted that

epidemiologic studies had reported positive associations between PM<sub>10-2.5</sub> and mortality or morbidity in a large number of cities across North America, Europe, and Asia, encompassing a variety of environments where PM<sub>10-2.5</sub> sources and composition are expected to vary widely. Though most of the available studies examined associations in urban areas, the Administrator noted that some studies had also linked mortality and morbidity with relatively high ambient concentrations of particles of non-urban crustal origin. In light of this body of available evidence, and consistent with the CASAC's advice, the Administrator concluded that it was appropriate to maintain a standard that provides some measure of protection against exposures to all thoracic coarse particles, regardless of their location, source of origin, or composition (78 FR 3176, January 15, 2013).

In next reaching the conclusion that it was appropriate to retain a PM<sub>10</sub> indicator for a standard meant to protect against exposures to ambient PM<sub>10-2.5</sub>, the Administrator noted that PM<sub>10</sub> mass includes both coarse PM (PM<sub>10-2.5</sub>) and fine PM (PM<sub>2.5</sub>). As a result, the concentration of PM<sub>10-2.5</sub> allowed by a PM<sub>10</sub> standard set at a single level declines as the concentration of PM<sub>2.5</sub> increases. Because PM<sub>2.5</sub> concentrations tend to be higher in urban areas than rural areas (e.g., Chan et al., 2018), the Administrator observed that a PM<sub>10</sub> standard would generally allow lower PM<sub>10-2.5</sub> concentrations in urban areas than in rural areas. She judged it appropriate to maintain such a standard given that much of the evidence for PM<sub>10-2.5</sub> toxicity, particularly at relatively low particle concentrations, came from study locations where thoracic coarse particles were of urban origin, and given the possibility that PM<sub>10-2.5</sub> contaminants in urban areas could increase particle toxicity. Thus, in the last review the Administrator concluded that it remained appropriate to maintain a standard that allows lower ambient concentrations of PM<sub>10-2.5</sub> in urban areas, where the evidence was strongest that exposure to thoracic coarse particles was associated with morbidity and mortality, and higher concentrations in non-urban areas, where the public health concerns were less certain. The Administrator concluded that the varying concentrations of coarse particles that would be permitted in urban versus non-urban areas under the 24-hour PM<sub>10</sub> standard, based on the varying levels of PM<sub>2.5</sub> present, appropriately reflected the differences in the strength of evidence regarding coarse particle health effects.

Finally, in specifically evaluating the degree of public health protection provided by the primary PM<sub>10</sub> standard, with its level of 150 µg/m<sup>3</sup> and its one-expected-exceedance form on average over three years, the Administrator recognized that the available health evidence and air quality information was much more limited for PM<sub>10-2.5</sub> than for PM<sub>2.5</sub>. In particular, the strongest evidence for health effects attributable to PM<sub>10-2.5</sub> exposure was for cardiovascular effects, respiratory effects, and/or premature mortality following short-term exposures. For each of these categories of effects, the 2009 ISA concluded that the evidence was “suggestive of a

causal relationship” (U.S. EPA, 2009, section 2.3.3). These determinations contrasted with those for PM<sub>2.5</sub>, as described in Chapter 3 above, which were determined in the ISA to be either “causal” or “likely to be causal” for mortality, cardiovascular effects, and respiratory effects (U.S. EPA, 2009, Tables 2-1 and 2-2).

The Administrator judged that the important uncertainties and limitations associated with the PM<sub>10-2.5</sub> evidence and information raised questions as to whether additional public health improvements would be achieved by revising the existing PM<sub>10</sub> standard. She specifically noted several uncertainties, including the following:

- (1) The number of epidemiologic studies that have employed copollutant models to address the potential for confounding, particularly by PM<sub>2.5</sub>, was limited. Therefore, the extent to which PM<sub>10-2.5</sub> itself, rather than one or more copollutants, contributes to reported health effects remained uncertain.
- (2) Only a limited number of experimental studies provided support for the associations reported in epidemiologic studies, resulting in further uncertainty regarding the plausibility of the associations between PM<sub>10-2.5</sub> and mortality and morbidity reported in epidemiologic studies.
- (3) Limitations in PM<sub>10-2.5</sub> monitoring data (i.e., limited data available from FRM/FEM sampling methods) and the different approaches used to estimate PM<sub>10-2.5</sub> concentrations across epidemiologic studies resulted in uncertainty in the ambient PM<sub>10-2.5</sub> concentrations at which the reported effects occur, increasing uncertainty in estimates of the extent to which changes in ambient PM<sub>10-2.5</sub> concentrations would likely impact public health.
- (4) While PM<sub>10-2.5</sub> effect estimates reported for mortality and morbidity were generally positive, most were not statistically significant, even in single-pollutant models. This included effect estimates reported in some study locations with PM<sub>10</sub> concentrations above those allowed by the current 24-hour PM<sub>10</sub> standard.
- (5) The composition of PM<sub>10-2.5</sub>, and the effects associated with various components, were also key uncertainties in the available evidence. Without more information on the chemical speciation of PM<sub>10-2.5</sub>, the apparent variability in associations across locations was difficult to characterize.

In considering these uncertainties, the Administrator particularly emphasized the considerable degree of uncertainty in the extent to which health effects reported in epidemiologic studies are due to PM<sub>10-2.5</sub> itself, as opposed to one or more co-occurring pollutants. This uncertainty reflected the relatively small number of PM<sub>10-2.5</sub> studies that had evaluated copollutant models, particularly copollutant models that included PM<sub>2.5</sub>, and the very limited body of controlled human exposure evidence supporting the plausibility of PM<sub>10-2.5</sub>-attributable adverse effects at ambient concentrations.

When considering the evidence as a whole, the Administrator concluded that the degree of public health protection provided by the current PM<sub>10</sub> standard against exposures to PM<sub>10-2.5</sub> should be maintained (i.e., neither increased nor decreased). The Administrator’s judgment that protection did not need to be increased was supported by her consideration of uncertainties in the overall body of evidence. Her judgment that the degree of public health protection provided by the current standard is not greater than warranted was supported by the observation that positive and statistically significant associations with mortality were reported in some single-city U.S. study locations likely to have violated the current PM<sub>10</sub> standard. Thus, the Administrator concluded that the existing 24-hour PM<sub>10</sub> standard, with its one-expected exceedance form on average over three years and a level of 150 µg/m<sup>3</sup>, was requisite to protect public health with an adequate margin of safety against effects that have been associated with PM<sub>10-2.5</sub>. In light of this conclusion, the EPA retained the existing PM<sub>10</sub> standard.

#### **4.1.2 Approach in the Current Review**

As discussed above for PM<sub>2.5</sub> (section 3.2.1), in this PA we place the greatest emphasis on effects for which the evidence has been determined to demonstrate a “causal” or a “likely to be causal” relationship with PM exposures (U.S. EPA, 2019). This approach focuses policy considerations and conclusions on health outcomes for which the evidence is strongest. Unlike for PM<sub>2.5</sub>, the ISA does not identify any PM<sub>10-2.5</sub>-related health outcomes for which the evidence supports either a “causal” or a “likely to be causal” relationship. Thus, for PM<sub>10-2.5</sub> this PA considers the evidence determined to be “suggestive of, but not sufficient to infer, a causal relationship,” recognizing the greater uncertainty in such evidence.

The preamble to the ISA states that “suggestive” evidence is “limited, and chance, confounding, and other biases cannot be ruled out” (U.S. EPA, 2015, Table II). In light of the additional uncertainty in the evidence for PM<sub>10-2.5</sub>-related health outcomes, compared to the evidence supporting “causal” or “likely to be causal” relationships for PM<sub>2.5</sub>, our approach to evaluating the primary PM<sub>10</sub> standard in this review is more limited than our approach to evaluating the primary PM<sub>2.5</sub> standards (discussed in Chapter 3). Specifically, our approach for PM<sub>10</sub> does not include evaluations of air quality distributions in locations of individual epidemiologic studies, comparisons of experimental exposures with ambient air quality, or the quantitative assessment of PM<sub>10-2.5</sub> health risks. The substantial uncertainty in such analyses, if they were to be conducted based on the currently available PM<sub>10-2.5</sub> health studies, would limit their utility for informing conclusions on the primary PM<sub>10</sub> standard. Therefore, as discussed further below, we focus our evaluation of the primary PM<sub>10</sub> standard on the overall body of evidence for PM<sub>10-2.5</sub>-related health effects. This includes consideration of the degree to which uncertainties in the evidence from the last review have been reduced and the degree to which

new uncertainties have been identified. In adopting this approach, we recognize that the Administrator's decisions as to whether to retain or revise the primary PM<sub>10</sub> standard will largely be public health policy judgments that will draw upon the scientific evidence for PM<sub>10-2.5</sub>-related health effects and judgments about how to consider the uncertainties and limitations inherent in that evidence.

## 4.2 EVIDENCE-BASED CONSIDERATIONS

This section draws from the EPA's synthesis and assessment of the scientific evidence presented in the ISA (U.S. EPA, 2019) to consider the following policy-relevant questions:

- **To what extent does the currently available scientific evidence strengthen, or otherwise alter, our conclusions from the last review regarding health effects attributable to long- or short-term PM<sub>10-2.5</sub> exposures? Have previously identified uncertainties been reduced? What important uncertainties remain and have new uncertainties been identified?**

Answers to these questions will inform our answer to the overarching question on the adequacy of the current primary PM<sub>10</sub> standard, posed at the beginning of this chapter. In section 4.2.1 below, we consider the nature of the effects attributable to long-term and short-term PM<sub>10-2.5</sub> exposures.

### 4.2.1 Nature of Effects

As noted above, for the health outcome categories and exposure duration combinations evaluated, the ISA concludes that the evidence supports causality determinations for PM<sub>10-2.5</sub> no stronger than "suggestive of, but not sufficient to infer, a causal relationship." These outcomes, along with their corresponding causality determinations from the 2009 ISA, are highlighted below in Table 4-1 (adapted from U.S. EPA, 2019, Table 1-4).

**Table 4-1. Key Causality Determinations for PM<sub>10-2.5</sub> Exposures**

Health Outcome	Exposure Duration	2009 PM ISA	2019 PM ISA
Mortality	Long-term	Inadequate	Suggestive of, but not sufficient to infer
	Short-term	Suggestive of, but not sufficient to infer	
Cardiovascular effects	Long-term	Inadequate	
	Short-term	Suggestive of, but not sufficient to infer	
Respiratory effects	Short-term	Suggestive of, but not sufficient to infer	
Cancer	Long-term	Inadequate	
Nervous System effects	Long-term	---	
Metabolic effects	Long-term	---	

While the evidence for some of the health outcomes listed in Table 4-1 has strengthened since the last review, the ISA concludes that overall “the uncertainties in the evidence identified in the 2009 PM ISA have, to date, still not been addressed” (U.S. EPA, 2019, section 1.4.2, p. 1-41). For example, epidemiologic studies available in the last review relied on various methods to estimate PM<sub>10-2.5</sub> exposures, and these methods had not been systematically compared to evaluate spatial and temporal correlations in exposure estimates. Methods included (1) calculating the difference between PM<sub>10</sub> and PM<sub>2.5</sub> concentrations at co-located monitors, (2) calculating the difference between county-wide averages of monitored PM<sub>10</sub> and PM<sub>2.5</sub> based on monitors that are not necessarily co-located, and (3) direct measurement of PM<sub>10-2.5</sub> using a dichotomous sampler (U.S. EPA, 2019, section 1.4.2). In the current review, more recent epidemiologic studies continue to use these approaches to estimate PM<sub>10-2.5</sub> concentrations. Additionally, some recent studies estimate long-term PM<sub>10-2.5</sub> exposures as the difference between PM<sub>10</sub> and PM<sub>2.5</sub> concentrations based on information from spatiotemporal or land use regression (LUR) models, in addition to monitors. As in the last review, the various methods used to estimate PM<sub>10-2.5</sub> concentrations have not been systematically evaluated (U.S. EPA, 2019, section 3.3.1.1), contributing to uncertainty regarding the spatial and temporal correlations in PM<sub>10-2.5</sub> concentrations across methods and in the PM<sub>10-2.5</sub> exposure estimates used in epidemiologic studies (U.S. EPA, 2019, section 2.5.1.2.3). Given the greater spatial and temporal variability of PM<sub>10-2.5</sub> and fewer PM<sub>10-2.5</sub> monitoring sites, compared to PM<sub>2.5</sub>, this uncertainty is particularly important for the coarse size fraction.

Beyond uncertainty associated with PM<sub>10-2.5</sub> exposure estimates in epidemiologic studies, the limited information on the potential for confounding by copollutants and the limited support available for the biological plausibility of serious effects following PM<sub>10-2.5</sub> exposures also continue to contribute broadly to uncertainty in the PM<sub>10-2.5</sub> health evidence. Uncertainty related to potential confounding stems from the relatively small number of epidemiologic studies that have evaluated PM<sub>10-2.5</sub> health effect associations in copollutants models with both gaseous pollutants and other PM size fractions. Uncertainty related to the biological plausibility of serious effects caused by PM<sub>10-2.5</sub> exposures results from the small number of controlled human exposure and animal toxicology<sup>1</sup> studies that have evaluated the health effects of experimental PM<sub>10-2.5</sub> inhalation exposures. The evidence supporting the ISA's "suggestive" causality determinations for PM<sub>10-2.5</sub>, including uncertainties in this evidence, is summarized in sections 4.2.1.1 to 4.2.1.6 below.

#### **4.2.1.1 Mortality**

##### Long-term exposures

Due to the dearth of studies examining the association between long-term PM<sub>10-2.5</sub> exposure and mortality, the 2009 PM ISA concluded that the evidence was "inadequate to determine if a causal relationship exists" (U.S. EPA, 2009). Since the completion of the 2009 ISA, some recent cohort studies conducted in the U.S. and Europe report positive associations between long-term PM<sub>10-2.5</sub> exposure and total (nonaccidental) mortality, though results are inconsistent across studies (U.S. EPA, 2019, Table 11-11). The examination of copollutant models in these studies remains limited and, when included, PM<sub>10-2.5</sub> effect estimates are often attenuated after adjusting for PM<sub>2.5</sub> (U.S. EPA, 2019, Table 11-11). Across studies, PM<sub>10-2.5</sub> exposure concentrations are estimated using a variety of approaches, including direct measurements from dichotomous samplers, calculating the difference between PM<sub>10</sub> and PM<sub>2.5</sub> concentrations measured at collocated monitors, and calculating difference of area-wide concentrations of PM<sub>10</sub> and PM<sub>2.5</sub>. As discussed above, temporal and spatial correlations between these approaches have not been evaluated, contributing to uncertainty regarding the potential for exposure measurement error (U.S. EPA, 2019, section 3.3.1.1 and Table 11-11). The ISA concludes that this uncertainty "reduces the confidence in the associations observed across studies" (U.S. EPA, 2019, p. 11-125). The ISA additionally concludes that the evidence for long-term PM<sub>10-2.5</sub> exposures and cardiovascular effects, respiratory morbidity, and metabolic disease provide limited biological plausibility for PM<sub>10-2.5</sub>-related mortality (U.S. EPA, 2019, sections 11.4.1 and 11.4). Taken together, the ISA concludes that, "this body of evidence is

---

<sup>1</sup> Compared to humans, smaller fractions of inhaled PM<sub>10-2.5</sub> penetrate into the thoracic regions of rats and mice (U.S. EPA, 2018, section 4.1.6), contributing to the relatively limited evaluation of PM<sub>10-2.5</sub> exposures in animal studies.

suggestive, but not sufficient to infer, that a causal relationship exists between long-term PM<sub>10-2.5</sub> exposure and total mortality” (U.S. EPA, 2019, p. 11-125).

#### Short-term exposures

The 2009 ISA concluded that the evidence is "suggestive of a causal relationship between short-term exposure to PM<sub>10-2.5</sub> and mortality” (U.S. EPA, 2009). Since the completion of the 2009 ISA, multicity epidemiologic studies conducted primarily in Europe and Asia continue to provide consistent evidence of positive associations between short-term PM<sub>10-2.5</sub> exposure and total (nonaccidental) mortality (U.S. EPA, 2019, Table 11-9). Although these studies contribute to increasing confidence in the PM<sub>10-2.5</sub>-mortality relationship, the use of a variety of approaches to estimate PM<sub>10-2.5</sub> exposures continues to contribute uncertainty to the associations observed. In addition, the ISA notes that an analysis by Adar et al. (2014) indicates “possible evidence of publication bias, which was not observed for PM<sub>2.5</sub>” (U.S. EPA, 2019, section 11.3.2, p. 11-106). Recent studies expand the assessment of potential copollutant confounding of the PM<sub>10-2.5</sub>-mortality relationship and provide evidence that PM<sub>10-2.5</sub> associations generally remain positive in copollutant models, though associations are attenuated in some instances (U.S. EPA, 2019, section 11.3.4.1, Figure 11-28, Table 11-10). The ISA concludes that, overall, the assessment of potential copollutant confounding is limited due to the lack of information on the correlation between PM<sub>10-2.5</sub> and gaseous pollutants and the small number of locations in which copollutant analyses have been conducted. Associations with cause-specific mortality provide some support for associations with total (nonaccidental) mortality, though associations with cause-specific mortality, particularly respiratory mortality, are more uncertain (i.e., wider confidence intervals) and less consistent (U.S. EPA, 2019, section 11.3.7). The ISA concludes that the evidence for PM<sub>10-2.5</sub>-related cardiovascular and respiratory effects provides only limited support for the biological plausibility of a relationship between short-term PM<sub>10-2.5</sub> exposure and cardiovascular mortality (U.S. EPA, 2019, Section 11.3.7). Based on the overall evidence, the ISA concludes that, “this body of evidence is suggestive, but not sufficient to infer, that a causal relationship exists between short-term PM<sub>10-2.5</sub> exposure and total mortality” (U.S. EPA, 2019, p. 11-120).

#### **4.2.1.2 Cardiovascular Effects**

##### Long-term exposures

In the 2009 PM ISA, the evidence describing the relationship between long-term exposure to PM<sub>10-2.5</sub> and cardiovascular effects was characterized as “inadequate to infer the presence or absence of a causal relationship.” The limited number of epidemiologic studies reported contradictory results and experimental evidence demonstrating an effect of PM<sub>10-2.5</sub> on the cardiovascular system was lacking (U.S. EPA, 2019, section 6.4).

The evidence relating long-term PM<sub>10-2.5</sub> exposures to cardiovascular mortality remains limited, with no consistent pattern of associations across studies and, as discussed above, uncertainty stemming from the use of various approaches to estimate PM<sub>10-2.5</sub> concentrations (U.S. EPA, 2019, Table 6-70). The evidence for associations with cardiovascular morbidity has grown and, while results across studies are not entirely consistent, some epidemiologic studies report positive associations with ischemic heart disease (IHD) and myocardial infarction (MI) (U.S. EPA, 2019, Figure 6-34); stroke (U.S. EPA, 2019, Figure 6-35); atherosclerosis; venous thromboembolism (VTE); and blood pressure and hypertension (U.S. EPA, 2019, Section 6.4.6). PM<sub>10-2.5</sub> cardiovascular mortality effect estimates are often attenuated, but remain positive, in copollutants models that adjust for PM<sub>2.5</sub>. For morbidity outcomes, associations are inconsistent in copollutant models that adjust for PM<sub>2.5</sub>, NO<sub>2</sub>, and chronic noise pollution (U.S. EPA, 2019, p. 6-276). The lack of toxicological evidence for long-term PM<sub>10-2.5</sub> exposures represents a substantial data gap (U.S. EPA, 2019, section 6.4.10), resulting in the ISA conclusion that “evidence from experimental animal studies is of insufficient quantity to establish biological plausibility” (U.S. EPA, 2019, p. 6-277). Based largely on the observation of positive associations in some high-quality epidemiologic studies, the ISA concludes that “evidence is suggestive of, but not sufficient to infer, a causal relationship between long-term PM<sub>10-2.5</sub> exposure and cardiovascular effects” (U.S. EPA, 2019, p. 6-277).

#### Short-term exposures

The 2009 ISA found that the available evidence for short-term PM<sub>10-2.5</sub> exposure and cardiovascular effects was “suggestive of a causal relationship.” This conclusion was based on several epidemiologic studies reporting associations between short-term PM<sub>10-2.5</sub> exposure and cardiovascular effects, including IHD hospitalizations, supraventricular ectopy, and changes in heart rate variability (HRV). In addition, dust storm events resulting in high concentrations of crustal material were linked to increases in total cardiovascular disease emergency department visits and hospital admissions. However, the 2009 ISA noted the potential for exposure measurement error and copollutant confounding in these epidemiologic studies. In addition, there was only limited evidence of cardiovascular effects from a small number of experimental studies (e.g. animal toxicological studies and controlled human exposure studies) that examined short-term PM<sub>10-2.5</sub> exposures (U.S. EPA, 2009, section 6.2.12.2). In the last review, key uncertainties included the potential for exposure measurement error, copollutant confounding, and limited evidence of biological plausibility for cardiovascular effects following inhalation exposure (U.S. EPA, 2019, section 6.3.13).

The evidence for short-term PM<sub>10-2.5</sub> exposure and cardiovascular outcomes has expanded since the last review, though important uncertainties remain. The ISA notes that there are a small number of epidemiologic studies reporting positive associations between short-term exposure to

PM<sub>10-2.5</sub> and cardiovascular-related morbidity outcomes. However, there is limited evidence to suggest that these associations are biologically plausible, or independent of copollutant confounding. The ISA also concludes that it remains unclear how the approaches used to estimate PM<sub>10-2.5</sub> concentrations in epidemiologic studies may impact exposure measurement error. Taken together, the ISA concludes that “the evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term PM<sub>10-2.5</sub> exposures and cardiovascular effects” (U.S. EPA, 2019, p.6-254).

#### **4.2.1.3 Respiratory Effects**

##### Short-term exposures

Based on a small number of epidemiologic studies observing associations with some respiratory effects and limited evidence from experimental studies to support biological plausibility, the 2009 ISA (U.S. EPA, 2009) concluded that the relationship between short-term exposure to PM<sub>10-2.5</sub> and respiratory effects is “suggestive of a causal relationship.” Epidemiologic findings were consistent for respiratory infection and combined respiratory-related diseases, but not for COPD. Studies were characterized by overall uncertainty in the exposure assignment approach and limited information regarding potential copollutant confounding. Controlled human exposure studies of short-term PM<sub>10-2.5</sub> exposures found no lung function decrements and inconsistent evidence for pulmonary inflammation. Animal toxicological studies were limited to those using non-inhalation (e.g., intra-tracheal instillation) routes of PM<sub>10-2.5</sub> exposure.

Recent epidemiologic findings consistently link PM<sub>10-2.5</sub> exposure to asthma exacerbation and respiratory mortality, with some evidence that associations remain positive (though attenuated in some studies of mortality) in copollutant models that include PM<sub>2.5</sub> or gaseous pollutants. Studies provide limited evidence for positive associations with other respiratory outcomes, including COPD exacerbation, respiratory infection, and combined respiratory-related diseases (U.S. EPA, 2019, Table 5-36). As noted above for other endpoints, an uncertainty in these epidemiologic studies is the lack of a systematic evaluation of the various methods used to estimate PM<sub>10-2.5</sub> concentrations and the resulting uncertainty in the spatial and temporal variability in PM<sub>10-2.5</sub> concentrations compared to PM<sub>2.5</sub> (U.S. EPA, 2019, sections 2.5.1.2.3 and 3.3.1.1). Taken together, the ISA concludes that “the collective evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term PM<sub>10-2.5</sub> exposure and respiratory effects” (U.S. EPA, 2019, p. 5-270).

#### **4.2.1.4 Cancer**

##### Long-term exposures

In the last review, little information was available from studies of cancer following inhalation exposures to PM<sub>10-2.5</sub>. Thus, the 2009 ISA determined the evidence was “inadequate to assess the relationship between long-term PM<sub>10-2.5</sub> exposures and cancer” (U.S. EPA, 2009). Since the 2009 ISA, the assessment of long-term PM<sub>10-2.5</sub> exposure and cancer remains limited, with a few recent epidemiologic studies reporting positive, but imprecise, associations with lung cancer incidence. Uncertainty remains in these studies with respect to exposure measurement error due to the use of PM<sub>10-2.5</sub> predictions that have not been validated by monitored PM<sub>10-2.5</sub> concentrations (U.S. EPA, 2019, sections 3.3.2.3 and 10.3.4). Relatively few experimental studies of PM<sub>10-2.5</sub> have been conducted, though available studies indicate that PM<sub>10-2.5</sub> exhibits two key characteristics of carcinogens: genotoxicity and oxidative stress. While limited, such experimental studies provide some evidence of biological plausibility for the findings in a small number of epidemiologic studies (U.S. EPA, 2019, section 10.3.4).

Taken together, the small number of epidemiologic and experimental studies, along with uncertainty with respect to exposure measurement error, contribute to the determination in the ISA that, “the evidence is suggestive of, but not sufficient to infer, a causal relationship between long-term PM<sub>10-2.5</sub> exposure and cancer” (U.S. EPA, 2019, p. 10-87).

#### **4.2.1.5 Metabolic Effects**

##### Long-term exposures

The 2009 ISA did not make a causality determination for PM<sub>10-2.5</sub>-related metabolic effects. Since the last review, one epidemiologic study shows an association between long-term PM<sub>10-2.5</sub> exposure and incident diabetes, while additional cross-sectional studies report associations with effects on glucose or insulin homeostasis (U.S. EPA, 2019, section 7.4). As discussed above for other outcomes, uncertainties with the epidemiologic evidence include the potential for copollutant confounding and exposure measurement error (U.S. EPA, 2019, Tables 7-14 and 7-15). The evidence base to support the biological plausibility of metabolic effects following PM<sub>10-2.5</sub> exposures is limited, but a cross-sectional study that investigated biomarkers of insulin resistance and systemic and peripheral inflammation may support a pathway leading to type 2 diabetes (U.S. EPA, 2019, sections 7.4.1 and 7.4.3). Based on the expanded, though still limited evidence base, the ISA concludes that, “[o]verall, the evidence is suggestive of, but not sufficient to infer, a causal relationship between [long]-term PM<sub>10-2.5</sub> exposure and metabolic effects” (U.S. EPA, 2019, p. 7-56).

#### **4.2.1.6 Nervous system effects**

##### Long-term exposures

The 2009 ISA did not make a causality determination for PM<sub>10-2.5</sub>-related nervous system effects. In the current review, newly available epidemiologic studies report associations between

PM<sub>10-2.5</sub> and impaired cognition and anxiety in adults in longitudinal analyses (U.S. EPA, 2019, Table 8-25, section 8.4.5). Associations of long-term exposure with neurodevelopmental effects are not consistently reported in children (U.S. EPA, 2019, sections 8.4.4 and 8.4.5). Uncertainties in these studies include the potential for copollutant confounding, as no studies examined copollutants models (U.S. EPA, 2019, section 8.4.5), and for exposure measurement error, given the use of various model-based subtraction methods to estimate PM<sub>10-2.5</sub> concentrations (U.S. EPA, 2019, Table 8-25). In addition, there is only limited animal toxicological evidence supporting the biological plausibility of nervous system effects (U.S. EPA, 2019, sections 8.4.1 and 8.4.5). Overall, the ISA concludes that, “the evidence is suggestive of, but not sufficient to infer, a causal relationship between long-term PM<sub>10-2.5</sub> exposure and nervous system effects (U.S. EPA, 2019, p. 8-75).

#### **4.2.1.7 Conclusions Drawn from the Evidence**

Based on the evidence available in the current review, as assessed in the ISA (U.S. EPA, 2019) and summarized in 4.2.1.1 to 4.2.1.6 above, we revisit the policy-relevant questions posed at the beginning of this section:

- **To what extent does the currently available scientific evidence strengthen, or otherwise alter, our conclusions from the last review regarding health effects attributable to long- or short-term PM<sub>10-2.5</sub> exposures? Have previously identified uncertainties been reduced? What important uncertainties remain and have new uncertainties been identified?**

In the last review, the strongest evidence for PM<sub>10-2.5</sub>-related health effects was for cardiovascular effects, respiratory effects, and premature mortality following short-term exposures. For each of these categories of effects, the ISA concluded that the evidence was “suggestive of a causal relationship” (U.S. EPA, 2009, section 2.3.3). As summarized in the sections above, key uncertainties in the evidence resulted from limitations in the approaches used to estimate ambient PM<sub>10-2.5</sub> concentrations in epidemiologic studies, limited examination of the potential for confounding by co-occurring pollutants, and limited support for the biological plausibility of the serious effects reported in many epidemiologic studies. Since 2009, the evidence base for several PM<sub>10-2.5</sub>-related health effects has expanded, broadening our understanding of the range of health effects linked to PM<sub>10-2.5</sub> exposures. This includes expanded evidence for the relationships between long-term exposures and cardiovascular effects, metabolic effects, nervous system effects, cancer, and mortality. However, key limitations in the evidence that were identified in the 2009 ISA persist in studies that have become available since the last review. These limitations include the following:

- The use of a variety of methods to estimate PM<sub>10-2.5</sub> exposures in epidemiologic studies and the lack of systematic evaluation of these methods, together with the relatively high

spatial and temporal variability in ambient PM<sub>10-2.5</sub> concentrations and the small number of monitoring sites, results in uncertainty in exposure estimates;

- The limited number of studies that evaluate PM<sub>10-2.5</sub> health effect associations in copollutant models, together with evidence from some studies for attenuation of associations in such models, results in uncertainty in the independence of PM<sub>10-2.5</sub> health effect associations from co-occurring pollutants;
- The limited number of controlled human exposure and animal toxicology studies of PM<sub>10-2.5</sub> inhalation contributes to uncertainty in the biological plausibility of the PM<sub>10-2.5</sub>-related effects reported in epidemiologic studies.

Thus, while new evidence is available for a broader range of health outcomes in the current review, that evidence is subject to the same types of uncertainties that were identified in the last review of the PM NAAQS. As in the last review, these uncertainties contribute to the conclusions in the ISA that the evidence for the PM<sub>10-2.5</sub>-related health effects discussed in this section is “suggestive of, but not sufficient to infer” causal relationships.

### **4.3 CASAC ADVICE AND PUBLIC COMMENTS**

As part of its review of the draft PA, the CASAC has provided advice on the adequacy of the public health protection afforded by the current primary PM<sub>10</sub> standard. As for PM<sub>2.5</sub> (section 3.4), the CASAC’s advice is documented in a letter sent to the EPA Administrator (Cox, 2019).

In its comments on the draft PA, the CASAC concurs with the draft PA’s overall preliminary conclusions that it is appropriate to consider retaining the current primary PM<sub>10</sub> standard without revision, stating that “[t]he CASAC agrees with the EPA conclusion that ‘...the available evidence does not call into question the adequacy of the public health protection afforded by the current primary PM<sub>10</sub> standard and that evidence supports considering of retaining the current standard in this review’” (Cox, 2019, p.3 of letter). The CASAC finds the more limited approach taken for PM<sub>10</sub>, compared to PM<sub>2.5</sub>, to be “reasonable and appropriate” given the less certain evidence and the conclusion that “key uncertainties identified in the last review remain” (Cox, 2019, p. 13 of consensus responses). To reduce these uncertainties in future reviews, the CASAC recommends improvements to PM<sub>10-2.5</sub> exposure assessment, including a more extensive network for direct monitoring of the PM<sub>10-2.5</sub> fraction (Cox, 2019, p. 13 of consensus responses). The CASAC also recommends additional human clinical and animal toxicology studies of the PM<sub>10-2.5</sub> fraction to improve the understanding of biological causal mechanisms and pathways (Cox, 2019, p. 13 of consensus responses).

We also received a limited number of public comments on the adequacy of the primary PM<sub>10</sub> standard. Of those who provided comments on the PM<sub>10</sub> standard, most commenters support the preliminary conclusion that it is appropriate to consider retaining the current PM<sub>10</sub> standard, without revision. One group that includes members of the academic research

community (i.e., the Independent PM Review Panel), however, supports lowering the level of the primary PM<sub>10</sub> standard, consistent with their recommendation to also lower the level of the 24-hour primary PM<sub>2.5</sub> standard.

#### **4.4 CONCLUSIONS ON THE ADEQUACY OF THE CURRENT STANDARD**

This section describes our conclusions regarding the adequacy of the current primary PM<sub>10</sub> standard. Our approach to reaching conclusions considers the EPA's assessment of the current scientific evidence for PM<sub>10-2.5</sub>-related health effects in the ISA and takes into account the advice received from the CASAC (Cox, 2019) and comments from the members of the public. We revisit the overarching question for this chapter:

- **Does the currently available scientific evidence support or call into question the adequacy of the protection afforded by the current primary PM<sub>10</sub> standard against health effects associated with exposures to PM<sub>10-2.5</sub>?**

In answering this question, we consider the currently available evidence within the context of the rationale supporting the decision in the last review to retain the primary PM<sub>10</sub> standard. We recognize that a final decision on the primary PM<sub>10</sub> standard in the current review will be largely a public health policy judgement in which the Administrator weighs the evidence, including its associated uncertainties.

As discussed in section 4.1.1 above, the decision to retain the primary PM<sub>10</sub> standard in the last review recognized the importance of maintaining some degree of protection against PM<sub>10-2.5</sub> exposures, given the evidence for PM<sub>10-2.5</sub>-related health effects, but noted uncertainties in the potential public health implications of revising the existing PM<sub>10</sub> standard. Regarding evidence for PM<sub>10-2.5</sub>-related health effects, the decision noted that epidemiologic studies had reported positive associations between PM<sub>10-2.5</sub> and mortality or morbidity in cities across North America, Europe, and Asia, encompassing a variety of environments where PM<sub>10-2.5</sub> sources and composition are expected to vary widely. Although most of these studies examined PM<sub>10-2.5</sub> health effect associations in urban areas, some studies had also linked mortality and morbidity with relatively high ambient concentrations of particles of non-urban crustal origin. Drawing from this evidence, it was judged appropriate to maintain a standard that provides some measure of protection against exposures to PM<sub>10-2.5</sub>, regardless of location, source of origin, or particle composition (78 FR 3176, January 15, 2013). As discussed above in section 4.1.1, it was further judged appropriate to retain the PM<sub>10</sub> indicator given that the varying concentrations of PM<sub>10-2.5</sub> permitted in urban versus non-urban areas under a PM<sub>10</sub> standard, based on the varying levels of PM<sub>2.5</sub> present (i.e., lower PM<sub>10-2.5</sub> concentrations allowed in urban areas, where PM<sub>2.5</sub> concentrations tend to be higher), appropriately reflected differences in the strength of PM<sub>10-2.5</sub>

health effects evidence. With regard to uncertainties, limitations in the estimates of ambient  $PM_{10-2.5}$  used in epidemiologic studies, the limited evaluation of copollutant models to address the potential for confounding, and the limited number of experimental studies supporting biologically plausible pathways for  $PM_{10-2.5}$ -related effects were all highlighted. These and other limitations in the  $PM_{10-2.5}$  evidence raised questions as to whether additional public health improvements would be achieved by revising the existing  $PM_{10}$  standard.

Since the last review, the evidence for several  $PM_{10-2.5}$ -related health effects has expanded, particularly for long-term exposures, broadening our understanding of the range of effects linked to  $PM_{10-2.5}$  exposures. As in the last review, epidemiologic studies continue to report positive associations with mortality or morbidity in cities across North America, Europe, and Asia, where  $PM_{10-2.5}$  sources and composition are expected to vary widely. Such studies provide an important part of the body of evidence supporting the strengthened causality determinations (and new determinations) for long-term  $PM_{10-2.5}$  exposures and mortality, cardiovascular effects, metabolic effects, nervous system effects and cancer (U.S. EPA, 2019). Thus, the scientific evidence that has become available since the last review does not call into question the decision in that review to maintain a primary standard that provides some measure of public health protection against  $PM_{10-2.5}$  exposures, regardless of location, source of origin, or particle composition. In addition, recent epidemiologic studies do not call into question the judgment in the last review that it is appropriate to retain the  $PM_{10}$  indicator, given that the varying concentrations of coarse particles permitted in urban versus non-urban areas under a  $PM_{10}$  standard (i.e., based on the varying concentrations of  $PM_{2.5}$  present) appropriately reflect the differences in the strength of evidence regarding coarse particle health effects.

As in the last review, important uncertainties remain in the evidence base for  $PM_{10-2.5}$ -related health effects. As summarized in section 4.2.1 above, these include uncertainties in the  $PM_{10-2.5}$  exposure estimates used in epidemiologic studies, in the independence of  $PM_{10-2.5}$  health effect associations, and in the biological plausibility of the  $PM_{10-2.5}$ -related effects. Thus, the evidence available in the current review is subject to the same broad uncertainties as were present in the last review. Consistent with the assessment of the evidence in the 2009 ISA (U.S. EPA, 2009), these uncertainties contribute to the determinations in the current ISA that the evidence for key  $PM_{10-2.5}$ -related health effects is “suggestive of, but not sufficient to infer” causal relationships (U.S. EPA, 2019). Drawing from this information, we reach the conclusion that, as in the last review, such uncertainties raise questions regarding the degree to which additional public health improvements would be achieved by revising the existing  $PM_{10}$  standard.

When the above information is taken together, we reach the conclusion that the available evidence does not call into question the scientific judgments that informed the decision in the last

review to retain the current primary PM<sub>10</sub> standard in order to protect against PM<sub>10-2.5</sub> exposures. Specifically, while the available evidence supports maintaining a PM<sub>10</sub> standard to provide some measure of protection against PM<sub>10-2.5</sub> exposures, uncertainties in the evidence lead to questions regarding the potential public health implications of revising the existing PM<sub>10</sub> standard. Thus, consistent with the approach taken in the last review and with the advice from the CASAC in this review, we reach the conclusions that the available evidence does not call into question the adequacy of the public health protection afforded by the current primary PM<sub>10</sub> standard and that evidence supports consideration of retaining the current standard in this review. As such, we have not evaluated alternative standards in this PA.

## **4.5 AREAS FOR FUTURE RESEARCH AND DATA COLLECTION**

As discussed above, a number of key uncertainties and limitations in the health evidence have been considered in this review. In this section, we highlight areas for future health-related research and data collection activities to address these uncertainties and limitations in the current body of evidence. These efforts, if undertaken, could provide important evidence for informing future reviews of the PM NAAQS. Key areas for future research efforts are summarized below.

- The body of experimental inhalation studies of exposure to PM<sub>10-2.5</sub> (e.g., controlled human exposure and animal toxicology studies) is currently relatively sparse. While coarse PM inhalation studies in rats and mice are complicated by substantial differences in dosimetry (i.e., compared to humans), additional experimental studies of short- or long-term PM<sub>10-2.5</sub> exposures could play an important role in weight of evidence judgments in future ISAs. Experimental evaluation of effects that are plausibly related to the serious health outcomes documented in epidemiologic studies could be particularly informative. Such effects could include changes in markers of cardiovascular or respiratory function, similar to the effects that have been evaluated following PM<sub>2.5</sub> exposures (e.g., vascular function, blood pressure, heart rate and heart rate variability, markers of potential for coagulation, systemic and respiratory inflammation, respiratory function, etc.).
- The potential for exposure error is of particular concern for PM<sub>10-2.5</sub>, given its less homogeneous atmospheric distribution compared to fine particles (U.S. EPA, 2019, section 1.2.1.5) and the relatively sparse PM<sub>10-2.5</sub> monitoring network. Therefore, efforts to develop and validate new exposure estimation approaches, or to further validate existing approaches, would be informative.
- Existing epidemiologic studies have rarely examined associations with PM<sub>10-2.5</sub> in copollutant models, contributing to uncertainty in the degree to which reported health effect associations are independent of potential confounding variables. Additional epidemiologic studies that evaluate copollutants models would be informative.
- Epidemiologic studies currently use a variety of approaches to measure/estimate PM<sub>10-2.5</sub> concentrations, including: (1) difference method with co-located monitors, (2) difference method with area-wide averages of monitored PM<sub>10</sub> and PM<sub>2.5</sub>, (3) difference method

with area-wide averages of modeled PM<sub>10</sub> and PM<sub>2.5</sub> or (4) direct measurement of PM<sub>10-2.5</sub> using a dichotomous sampler. It is important that we better understand how these methods compare to one another, both in terms of absolute estimated concentrations and in terms of the spatial and temporal correlations in those estimated concentrations between methods.

- Measurement capabilities and the availability of PM<sub>10-2.5</sub> ambient concentration data have greatly increased since the 2009 ISA (U.S. EPA, 2019, section 2.5.1.1.3). Starting in 2011, PM<sub>10-2.5</sub> has been monitored at NCore stations, IMPROVE stations, and several sites run by State and local agencies. To date, epidemiologic studies have used a variety of approaches to measure/estimate PM<sub>10-2.5</sub> concentrations but have not used direct measurements from NCore or IMPROVE stations to evaluate health effects associations with PM<sub>10-2.5</sub> exposure. A body of epidemiologic studies that evaluate health effect associations using monitoring data from these stations could allow more direct comparisons of results across studies.
- Evaluate and expand the PM<sub>10-2.5</sub> network, along with speciation of PM<sub>10-2.5</sub> including multi-elements, major ions, carbon (including carbonate carbon), and bioaerosols
- Characterize PM<sub>10-2.5</sub> in different health-relevant exposure environments (e.g., city center, suburban, roadside, agricultural, and rural areas) for mass, elements (including potential toxic species), carbonaceous materials (including selected organic compounds and carbonate), water-soluble ions, and bioaerosols (including endotoxins, 1,3 beta glucan, and total protein).
- Additional areas of interest for future research include:
  - Further evaluation of the potential for particular PM<sub>10-2.5</sub> components, groups of components, or other particle characteristics to contribute to exposure-related health effects.
  - Research to improve our understanding of concentration-response relationships and the confidence bounds around these relationships, especially at lower ambient PM<sub>10-2.5</sub> concentrations.
  - Identifying novel populations that could be at-risk of PM<sub>10-2.5</sub>-related health effects.
  - Modeling to estimate PM<sub>10-2.5</sub> mass and composition in areas with sparse or less-than-daily monitoring.

## 5 REVIEW OF THE SECONDARY STANDARDS

This chapter presents key policy-relevant considerations and summary conclusions regarding the public welfare protection provided by the current secondary PM standards to protect against PM-related visibility impairment, climate effects, and materials effects. These considerations and conclusions are framed by a series of policy-relevant questions, including the following overarching question:

- **Does the currently available scientific evidence and quantitative information support or call into question the adequacy of the protection afforded by the current secondary PM standards?**

The answer to this question is informed by evaluation of a series of more specific policy-relevant questions, which expand upon those presented at the outset of this review in the IRP (U.S. EPA, 2016). Answers to these questions are intended to inform decisions by the Administrator on whether, and if so how, to revise the secondary PM standards.

Section 5.1 presents our approach for reviewing the secondary standards for PM. Section 5.2.1 presents our consideration of the available scientific evidence and our consideration of quantitative information for visibility effects, while section 5.2.2 considers the available scientific evidence for each of the non-visibility welfare effects (climate effects and materials effects) separately.<sup>1</sup> Section 5.3 summarizes the advice and recommendations received from the CASAC during its review of the draft PA, and by public comments received on the draft document. Conclusions regarding the public welfare protection provided by the current secondary PM standards are summarized in section 5.4. Section 5.5 discusses areas for future research and data collection to improve our understanding of PM-related welfare effects in future reviews.

### 5.1 APPROACH

In the last review of the PM NAAQS, completed in 2012, the EPA retained the secondary 24-hour PM<sub>2.5</sub> standard, with its level of 35 µg/m<sup>3</sup>, and the 24-hour PM<sub>10</sub> standard, with its level of 150 µg/m<sup>3</sup> (78 FR 3228, January 15, 2013). The EPA also retained the level, set at 15 µg/m<sup>3</sup>, and averaging time of the annual PM<sub>2.5</sub> standard, while revising the form. With regard to the

---

<sup>1</sup> Other welfare effects of PM, such as ecological effects, are being considered in the separate, on-going review of the secondary NAAQS for oxides of nitrogen and oxides of sulfur. Accordingly, the public welfare protection provided by the secondary PM standards against ecological effects such as those related to deposition of nitrogen- and sulfur-containing compounds in vulnerable ecosystems is being considered in that separate review. Thus, the Administrator's conclusion in this review will be focused only and specifically on the adequacy of public welfare protection provided by the secondary PM standards from effects related to visibility, climate, and materials.

form of the annual PM<sub>2.5</sub> standard, the EPA removed the option for spatial averaging (78 FR 3228, January 15, 2013). Key aspects of the Administrator’s decisions on the secondary PM standards for non-visibility effects and visibility effects are described below in section 5.1.1.

### **5.1.1 Approach Used in the Last Review**

The 2012 decision on the adequacy of the secondary PM standards was based on consideration of the protection provided by those standards for visibility and for the non-visibility effects of materials damage, climate effects and ecological effects. As noted earlier, the current review of the public welfare protection provided by the secondary PM standards against ecological effects is occurring in the separate, on-going review of the secondary NAAQS for oxides of nitrogen and oxides of sulfur. Thus, the consideration of ecological effects in the 2012 review is not discussed here. Rather, the sections below focus on the Administrator’s consideration of climate and materials effects (section 5.1.1.1) and visibility effects (section 5.1.1.2).

#### **5.1.1.1 Non-Visibility Effects**

With regard to the role of PM in climate, the Administrator considered whether it was appropriate to establish any distinct secondary PM standards to address welfare effects associated with climate impacts. In considering the scientific evidence, she noted the 2009 ISA conclusion “that a causal relationship exists between PM and effects on climate” and that aerosols<sup>2</sup> alter climate processes directly through radiative forcing and by indirect effects on cloud brightness, changes in precipitation, and possible changes in cloud lifetimes (U.S. EPA, 2009, section 9.3.10). Additionally, the major aerosol components with the potential to affect climate processes (i.e., black carbon (BC), organic carbon (OC), sulfates, nitrates and mineral dusts) vary in their reflectivity, forcing efficiencies, and direction of climate forcing (U.S. EPA, 2009, section 9.3.10).

Noting the strong evidence indicating that aerosols affect climate, the Administrator further considered what the available information indicated regarding the adequacy of protection provided by the secondary PM standards. She noted that a number of uncertainties in the scientific information affected our ability to quantitatively evaluate the standards in this regard.

---

<sup>2</sup> In the climate sciences research community, PM is encompassed by what is typically referred to as aerosol. An aerosol is defined as a solid or liquid suspended in a gas, but PM refers to the solid or liquid phase of an aerosol. In this review of the secondary PM NAAQS the discussion on climate effects of PM uses the term PM throughout for consistency with the ISA (U.S. EPA, 2019) as well as to emphasize that the climate processes altered by aerosols are generally altered by the PM portion of the aerosol. Exceptions to this practice include the discussion of climate effects in the last review, when aerosol was used when discussing suspending aerosol particles, and for certain acronyms that are widely used by the climate community that include the term aerosol (e.g., aerosol optical depth, or AOD).

For example, the ISA and PA noted the spatial and temporal heterogeneity of PM components that contribute to climate forcing, uncertainties in the measurement of aerosol components, inadequate consideration of aerosol impacts in climate modeling, insufficient data on local and regional microclimate variations and heterogeneity of cloud formations. In light of these uncertainties and the lack of sufficient data, the 2011 PA concluded that it was not feasible in the last review “to conduct a quantitative analysis for the purpose of informing revisions [to the secondary PM NAAQS] based on climate” (U.S. EPA, 2011, pp. 5-11 to 5-12) and that there was insufficient information available to base a national ambient air quality standard on climate impacts associated with ambient air concentrations of PM or its constituents (U.S. EPA, 2011, section 5.2.3). The Administrator agreed with this conclusion (78 FR 3225-3226, January 15, 2013).

With regard to materials effects, the Administrator also considered effects associated with the deposition of PM (i.e., dry and wet deposition), including both physical damage (materials effects) and aesthetic qualities (soiling effects). The deposition of PM can physically affect materials, adding to the effects of natural weathering processes, by promoting or accelerating the corrosion of metals; by degrading paints; and by deteriorating building materials such as stone, concrete, and marble (U.S. EPA, 2009, section 9.5). Additionally, the deposition of PM from ambient air can reduce the aesthetic appeal of buildings and objects through soiling. The ISA concluded that evidence was “sufficient to conclude that a causal relationship exists between PM and effects on materials” (U.S. EPA, 2009, sections 2.5.4 and 9.5.4). However, the 2011 PA noted that quantitative relationships were lacking between particle size, concentrations, and frequency of repainting and repair of surfaces and that considerable uncertainty exists in the contributions of co-occurring pollutants to materials damage and soiling processes (U.S. EPA, 2011, p. 5-29). The 2011 PA concluded that none of the evidence available in the last review called into question the adequacy of the existing secondary PM standards to protect against material effects (U.S. EPA, 2011, p. 5-29). The Administrator agreed with this conclusion (78 FR 3225-3226, January 15, 2013).

In considering non-visibility welfare effects in the last review, as discussed above, the Administrator concluded that, while it is important to maintain an appropriate degree of control of fine and coarse particles to address non-visibility welfare effects, “[i]n the absence of information that would support any different standards...it is appropriate to retain the existing suite of secondary standards” (78 FR 3225-3226, January 15, 2013). Her decision was consistent with the CASAC advice related to non-visibility effects. Specifically, the CASAC agreed with the 2011 PA conclusions that, while these effects are important, “there is not currently a strong technical basis to support revisions of the current standards to protect against these other welfare effects” (Samet, 2010, p. 5). Thus, the Administrator concluded that it was appropriate to retain

all aspects of the existing 24-hour PM<sub>2.5</sub> and PM<sub>10</sub> secondary standards. With regard to the secondary annual PM<sub>2.5</sub> standard, the Administrator concluded that it was appropriate to retain a level of 15.0 µg/m<sup>3</sup> while revising only the form of the standard to remove the option for spatial averaging (78 FR 3225-3226, January 15, 2013).

#### **5.1.1.2 Visibility Effects**

Having reached the conclusion to retain the existing secondary PM standards to protect against non-visibility welfare effects, the Administrator next considered the level of protection that would be requisite to protect public welfare against PM-related visibility impairment and whether to adopt a distinct secondary standard to achieve this level of protection. In reaching her final decision that the existing 24-hour PM<sub>2.5</sub> standard provides sufficient protection against PM-related visibility impairment (78 FR 3228, January 15, 2013), the Administrator considered the evidence assessed in the 2009 ISA (U.S. EPA, 2009) and the analyses included in the Urban-Focused Visibility Assessment (2010 UFVA; U.S. EPA, 2010) and the 2011 PA (U.S. EPA, 2011). She also considered the degree of protection for visibility that would be provided by the existing secondary standard, focusing specifically on the secondary 24-hour PM<sub>2.5</sub> standard with its level of 35 µg/m<sup>3</sup>. These considerations, and the Administrator's conclusions regarding visibility are discussed in more detail below.

In the last review, the ISA concluded that, “collectively, the evidence is sufficient to conclude that a causal relationship exists between PM and visibility impairment” (U.S. EPA, 2009, p. 2-28). Visibility impairment is caused by light scattering and absorption by suspended particles and gases, including water content of aerosols.<sup>3</sup> The available evidence in the last review indicated that specific components of PM have been shown to contribute to visibility impairment. For example, at sufficiently high relative humidity values, sulfate and nitrate are the PM components that scatter more light and thus contribute most efficiently to visibility impairment. Elemental carbon (EC) and OC are also important contributors, especially in the northwestern U.S. where their contribution to PM<sub>2.5</sub> mass is higher. Crustal materials can be significant contributors to visibility impairment, particularly for remote areas in the arid southwestern U.S. (U.S. EPA, 2009, section 2.5.1).

Visibility impairment can have implications for people's enjoyment of daily activities and for their overall sense of well-being (U.S. EPA, 2009, section 9.2). In consideration of the potential public welfare implication of various degrees of PM-related visibility impairment, the

---

<sup>3</sup> All particles scatter light and, although a larger particle scatters more light than a similarly shaped smaller particle of the same composition, the light scattered per unit of mass is greatest for particles with diameters from ~0.3-1.0 µm (U.S. EPA, 2009, section 2.5.1). Particles with hygroscopic components (e.g., particulate sulfate and nitrate) contribute more to light extinction at higher relative humidity than at lower relative humidity because they change size in the atmosphere in response to relative humidity.

Administrator considered the available visibility preference studies that were part of the overall body of evidence in the 2009 ISA and reviewed as a part of the 2010 UFVA. These preference studies provided information about the potential public welfare implications of visibility impairment from surveys in which participants were asked questions about their preferences or the values they placed on various visibility conditions, as displayed to them in scenic photographs or in images with a range of known light extinction levels.<sup>4</sup>

In noting the relationship between PM concentrations and PM-related light extinction, the Administrator focused on identifying an adequate level of protection against visibility-related welfare effects. She first concluded that a standard in terms of a PM<sub>2.5</sub> visibility index would provide a measure of protection against PM-related light extinction that directly takes into account the factors (i.e., species composition and relative humidity) that influence the relationship between PM<sub>2.5</sub> in ambient air and PM-related visibility impairment. A PM<sub>2.5</sub> visibility index standard would afford a relatively high degree of uniformity of visual air quality protection in areas across the country by directly incorporating the effects of differences of PM<sub>2.5</sub> composition and relative humidity. In defining a target level of protection in terms of a PM<sub>2.5</sub> visibility index, as discussed below, the Administrator considered specific elements of the index, including the basis for its derivation, as well as an appropriate averaging time, level, and form.

With regard to the basis for derivation of a visibility index, the Administrator concluded that it was appropriate to use an adjusted version of the original IMPROVE algorithm,<sup>5</sup> in conjunction with monthly average relative humidity data based on long-term climatological means. In so concluding, the Administrator noted the CASAC conclusion on the reasonableness of reliance on a PM<sub>2.5</sub> light extinction indicator calculated from PM<sub>2.5</sub> chemical composition and relative humidity. In considering alternative approaches for a focus on visibility, the Administrator recognized that the available mass monitoring methods did not include measurement of the full water content of ambient PM<sub>2.5</sub>, nor did they provide information on the composition of PM<sub>2.5</sub>, both of which contribute to visibility impacts (77 FR 38980, June 29, 2012). In addition, at the time of the proposal, the Administrator recognized that suitable equipment and performance-based verification procedures did not then exist for direct

---

<sup>4</sup> Preference studies were available in four urban areas in the last review. Three western preference studies were available, including one in Denver, Colorado (Ely et al., 1991), one in the lower Fraser River valley near Vancouver, British Columbia, Canada (Pryor, 1996), and one in Phoenix, Arizona (BBC Research & Consulting, 2003). A pilot focus group study was also conducted for Washington, DC (Abt Associates, 2001), and a replicate study with 26 participants was also conducted for Washington, DC (Smith and Howell, 2009). More details about these studies are available in Appendix D.

<sup>5</sup> The revised IMPROVE algorithm (Pitchford et al., 2007) uses major PM chemical composition measurements and relative humidity estimates to calculate light extinction. For more information about the derivation of and input data required for the original and revised IMPROVE algorithms, see 78 FR 3168-3177, January 15, 2013.

measurement of light extinction and could not be developed within the time frame of the review (77 FR 38980-38981, June 29, 2012).

With regard to the averaging time of the index, the Administrator concluded that a 24-hour averaging time would be appropriate for a visibility index (78 FR 3226, January 15, 2013). Although she recognized that hourly or sub-daily (4- to 6-hour) averaging times, within daylight hours and excluding hours with relatively high humidity, are more directly related to the short-term nature of the perception of PM-related visibility impairment and relevant exposure periods for segments of the viewing public than a 24-hour averaging time, she also noted that there were data quality uncertainties associated with the instruments used to provide the hourly PM<sub>2.5</sub> mass measurements required for an averaging time shorter than 24 hours. The Administrator also considered the results of analyses that compared 24-hour and 4-hour averaging times for calculating the index. These analyses showed good correlation between 24-hour and 4-hour average PM<sub>2.5</sub> light extinction, as evidenced by reasonably high city-specific and pooled R-squared values, generally in the range of over 0.6 to over 0.8. Based on these analyses and the 2011 PA conclusions regarding them, the Administrator concluded that a 24-hour averaging time would be a reasonable and appropriate surrogate for a sub-daily averaging time.

With regard to the statistical form of the index, the Administrator settled on a 3-year average of annual 90<sup>th</sup> percentile values. In so doing, she noted that a 3-year average form provided stability from the occasional effect of inter-annual meteorological variability that can result in unusually high pollution levels for a particular year (78 FR 3198, January 15, 2013; U.S. EPA, 2011, p. 4-58). Regarding the annual statistic to be averaged, the 2010 UFVA evaluated three different statistics: 90<sup>th</sup>, 95<sup>th</sup>, and 98<sup>th</sup> percentiles (U.S. EPA, 2010, chapter 4). In considering these alternative percentiles, the 2011 PA noted that the Regional Haze Program targets the 20 percent most impaired days for improvements in visual air quality in Federal Class I areas and that the median of the distribution of these 20 percent worst days would be the 90<sup>th</sup> percentile. The 2011 PA further noted that strategies that are implemented so that 90 percent of days would have visual air quality that is at or below the level of the standard would reasonably be expected to lead to improvements in visual air quality for the 20 percent most impaired days. Lastly, the 2011 PA recognized that the available studies on people's preferences did not address frequency of occurrence of different levels of visibility and did not identify a basis for a different target for urban areas than that for Class I areas (U.S. EPA, 2011, p. 4-59). These considerations led the Administrator to conclude that 90<sup>th</sup> percentile form was the most appropriate annual statistic to be averaged across three years (78 FR 3226, January 15, 2013).

With regard to the level of the index, the Administrator considered the visibility preferences studies conducted in four urban areas (U.S. EPA, 2011, p. 4-61). Based on these

studies, the PA identified a range of levels from 20 to 30 deciviews (dv)<sup>6</sup> as being a reasonable range of “candidate protection levels” (CPLs).<sup>7</sup> In considering this range of CPLs, the Administrator noted the uncertainties and limitations in public preference studies, including the small number of stated preference studies available; the relatively small number of study participants and the extent to which the study participants may not be representative of the broader study area population in some of the studies; and the variations in the specific materials and methods used in each study. She concluded that the substantial degrees of variability and uncertainty in the public preference studies should be reflected in a target protection level at the upper end of the range of CPLs than if the information were more consistent and certain. Therefore, the Administrator concluded that it was appropriate to set a target level of protection in terms of a 24-hour PM<sub>2.5</sub> visibility index at 30 dv (78 FR 3226-3227, January 15, 2013).

Based on her considerations and conclusions summarized above, the Administrator concluded that the protection provided by a secondary standard based on a 3-year visibility metric, defined in terms of a PM<sub>2.5</sub> visibility index with a 24-hour averaging time, a 90<sup>th</sup> percentile form averaged over 3 years, and a level of 30 dv, would be requisite to protect public welfare with regard to visual air quality (78 FR 3227, January 15, 2013). Having reached this conclusion, she next determined whether an additional distinct secondary standard in terms of a visibility index was needed given the degree of protection from visibility impairment afforded by the existing secondary standards. Specifically, she noted that the air quality analyses showed that all areas meeting the existing 24-hour PM<sub>2.5</sub> standard, with its level of 35 µg/m<sup>3</sup>, had visual air quality at least as good as 30 dv, based on the visibility index defined above (Kelly et al., 2012b, Kelly et al., 2012a). Thus, the secondary 24-hour PM<sub>2.5</sub> standard would likely be controlling relative to a 24-hour visibility index set at a level of 30 dv. Additionally, areas would be unlikely to exceed the target level of protection for visibility of 30 dv without also exceeding the existing secondary 24-hour standard. Thus, the Administrator judged that the 24-hour PM<sub>2.5</sub> standard “provides sufficient protection in all areas against the effects of visibility impairment – i.e., that the existing 24-hour PM<sub>2.5</sub> standard would provide *at least* the target level of protection for visual air quality of 30 dv which the Administrator judges appropriate” (78 FR 3227, January 15, 2013). She further judged that “[s]ince sufficient protection from visibility impairment would be provided for all areas of the country without adoption of a distinct secondary standard, and adoption of a distinct secondary standard will not change the degree of over-protection for some areas of the country...adoption of such a distinct secondary standard is not needed to provide

---

<sup>6</sup> Deciview (dv) refers to a scale for characterizing visibility that is defined directly in terms of light extinction. The deciview scale is frequently used in the scientific and regulatory literature on visibility.

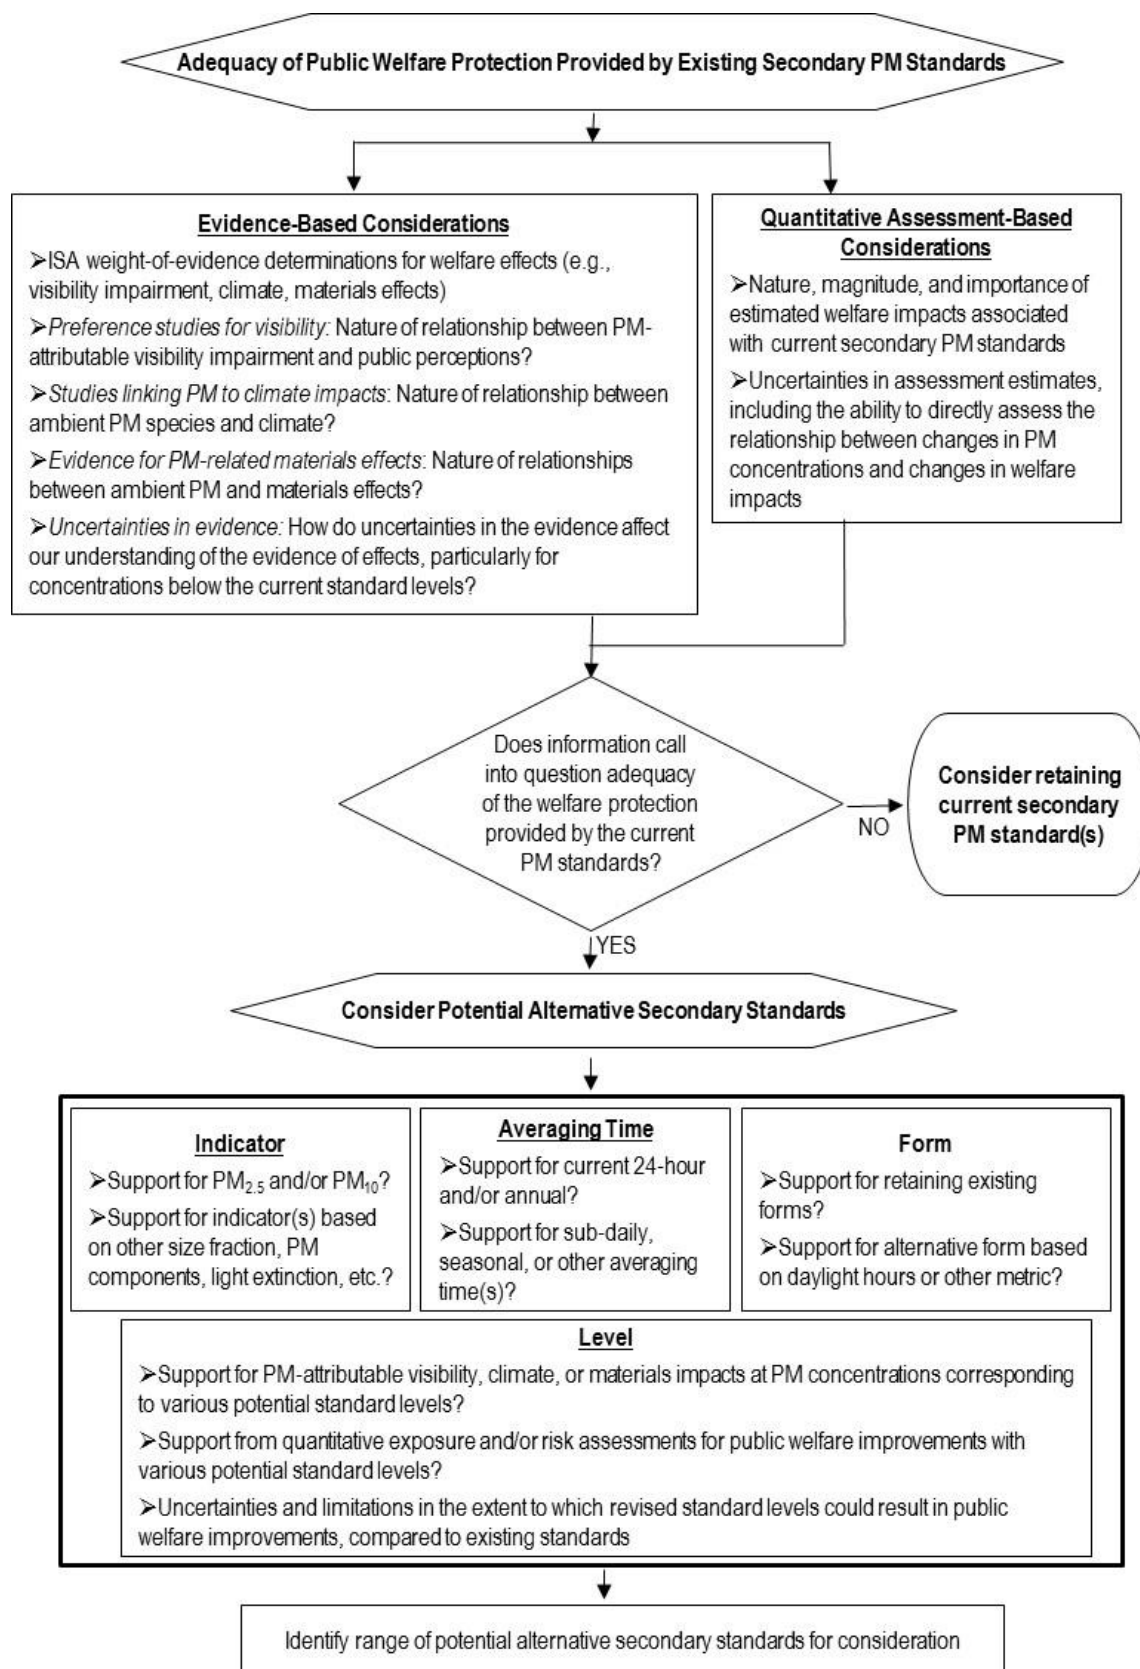

<sup>7</sup> For comparison, 20 dv, 25 dv, and 30 dv are equivalent to 64, 112, and 191 megameters (Mm<sup>-1</sup>), respectively.

requisite protection for both visibility and nonvisibility related welfare effects” (78 FR 3228, January 15, 2013).

### **5.1.2 General Approach Used in the Current Review**

To evaluate whether it is appropriate to consider retaining the current suite of secondary PM standards, or whether consideration of revision is appropriate, we have adopted an approach in this review that builds on the general approach used in the last review and reflects the body of evidence and information now available. As summarized above, past approaches have been based most fundamentally on using information from PM visibility studies and quantitative analyses of PM-related visibility impairment to inform the selection of secondary PM standards that, in the Administrator’s judgment, protect the public welfare from any known or anticipated effects. These fundamental considerations are again the basis for our approach in this review.

In conducting this assessment, we draw on the current evidence and quantitative assessments of visibility impairment associated with PM in ambient air. In considering the scientific and technical information, we consider both the information available at the time of the last review and information newly available since the last review, including the evidence assessed in the ISA and updated air quality-based analyses (Appendix D). Figure 5-1 below illustrates our general approach in developing conclusions regarding the adequacy of the current secondary standards and, as appropriate, potential alternative standards. In the boxes in Figure 5-1, the range of questions that we consider in sections 5.2.1 and 5.2.2 below are represented by a summary of policy-relevant questions that frame our consideration of the scientific evidence and quantitative analyses.

**Figure 5-1. Overview of general approach for review of secondary PM standards.**

## 5.2 ADEQUACY OF THE CURRENT SECONDARY PM STANDARDS

In considering the available evidence for welfare effects attributable to PM as presented in the ISA, this section poses the following policy-relevant questions:

- **Does the currently available scientific evidence and quantitative information support or call into question the adequacy of the welfare protection afforded by the current secondary PM standards?**

In answering this question, we have posed a series of more specific questions to aid in considering the currently available scientific evidence and quantitative information, as discussed below. In considering the scientific and technical information, we reflect upon both the information available in the last review and information that is newly available since the last review as assessed and presented in the ISA (U.S. EPA, 2019), focusing on welfare effects for which the evidence supports either a “causal” or a “likely to be causal” relationship as described in the Preamble to the ISA (U.S. EPA, 2015). Table 5-1 lists such causality determinations from the ISA for welfare effects. As in the last review, the evidence is sufficient to support a causal relationship between PM and visibility effects (section 5.2.1), climate effects (section 5.2.2) and materials effects (section 5.2.2).

**Table 5-1. Key causality determinations for PM-related welfare effects.**

Effect	2009 PM ISA	2019 PM ISA
Visibility effects	Causal	Causal
Climate effects	Causal	Causal
Materials effects	Causal	Causal

### 5.2.1 Visibility Effects

In the sections below, we consider the nature of visibility-related effects attributable to PM (section 5.2.1.1) and the quantitative information currently available (section 5.2.1.2).

#### 5.2.1.1 Evidence-Based Considerations

In considering the available evidence of visibility welfare effects attributable to PM as presented in the ISA, this section addresses the following policy-relevant questions:

- **Does the current evidence alter our conclusions from the last review regarding the nature of visibility effects attributable to PM in ambient air?**

Visibility refers to the visual quality of a human’s view with respect to color rendition and contrast definition. It is the ability to perceive landscape form, colors, and textures. Visibility involves optical and psychophysical properties involving human perception, judgment, and interpretation. Light between the observer and the object can be scattered into or out of the sight

path and absorbed by PM or gases in the sight path. As recognized above, the conclusion of the ISA that “the evidence is sufficient to conclude that a causal relationship exists between PM and visibility impairment” is consistent with conclusions of causality in the last review (U.S. EPA, 2019, section 13.2.6). These conclusions are based on strong and consistent evidence that ambient PM can impair visibility in both urban and remote areas (U.S. EPA, 2009, section 9.2.5).

These subsequent questions consider the characterization and quantification of light extinction and preferences associated with varying degrees of visibility impairment.

- **To what extent is new information available that changes or enhances our understanding of the physics of light extinction and/or its quantification (e.g., through light extinction or other monitoring methods or through algorithms such as IMPROVE)?**

Our understanding of the relationship between light extinction and PM mass has changed little since the 2009 ISA (U.S. EPA, 2009). The combined effect of light scattering and absorption by particles and gases is characterized as light extinction, i.e., the fraction of light that is scattered or absorbed per unit of distance in the atmosphere. Light extinction is measured in units of 1/distance, which is often expressed in the technical literature as visibility per megameter (abbreviated  $\text{Mm}^{-1}$ ). Higher values of light extinction (usually given in terms of  $\text{Mm}^{-1}$  or  $\text{dv}$ ) correspond to lower visibility. When PM is present in the air, its contribution to light extinction is typically much greater than that of gases (U.S. EPA, 2019, section 13.2.1). The impact of PM on light scattering depends on particle size and composition, as well as relative humidity. All particles scatter light, as described by the Mie theory, which relates light scattering to particle size, shape and index of refraction (U.S. EPA, 2019, section 13.2.3; Van de Hulst, 1981; Mie, 1908). Fine particles scatter more light than coarse particles on a per unit mass basis and include sulfates, nitrates, organics, light-absorbing carbon, and soil (Malm et al., 1994). Hygroscopic particles like ammonium sulfate, ammonium nitrate, and sea salt increase in size as relative humidity increases, leading to increased light scattering (U.S. EPA, 2019, section 13.2.3).

Direct measurements of PM light extinction, scattering, and absorption are considered more accurate for quantifying visibility impairment than PM mass-based estimates because they do not depend on assumptions about particle characteristics (e.g., size, shape, density, component mixture, etc.). Measurements of light extinction can be made with high time resolution, allowing for characterization of subdaily temporal patterns of visibility impairment. Measurement methods include transmissometers for measurement of light extinction and the determination of visual range and integrating nephelometers for measurement of light scattering, as well as teleradiometers and telephotometers, and photography and photographic modeling (U.S. EPA, 2009; U.S. EPA, 2004). While some recent research confirms and adds to the body of knowledge

available regarding direct measurements as is described in the ISA, no major new developments have been made with these measurement methods since the last review (U.S. EPA, 2019, section 13.2.2.2).

A theoretical relationship between light extinction and PM characteristics has been derived from Mie theory (U.S. EPA, 2019, Equation 13-5) and can be used to estimate light extinction by combining mass scattering efficiencies of particles with particle concentrations (U.S. EPA, 2019, section 13.2.3; U.S. EPA, 2009, sections 9.2.2.2 and 9.2.3.1). However, routine ambient air monitoring rarely includes measurements of particle size and composition information with sufficient detail for these calculations. Accordingly, a much simpler algorithm has been developed to make estimating light extinction more practical.

This algorithm, known as the IMPROVE algorithm,<sup>8</sup> provides for the estimation of light extinction ( $b_{ext}$ ), in units of  $Mm^{-1}$ , using routinely monitored components of fine ( $PM_{2.5}$ ) and coarse ( $PM_{10-2.5}$ ) PM. Relative humidity data are also needed to estimate the contribution by liquid water that is in solution with the hygroscopic components of PM. To estimate each component's contribution to light extinction, their concentrations are multiplied by extinction coefficients and are additionally multiplied by a water growth factor that accounts for their expansion with moisture. Both the extinction efficiency coefficients and water growth factors of the IMPROVE algorithm have been developed by a combination of empirical assessment and theoretical calculation using particle size distributions associated with each of the major aerosol components (U.S. EPA, 2019, section 13.2.3.1, section 13.2.3.3).

The *original IMPROVE algorithm* (Equation D-1 in Appendix D), so referenced here to distinguish it from subsequent variations developed later, was found to underestimate the highest light scattering values and overestimate the lowest values at IMPROVE monitors throughout the U.S. (Malm and Hand, 2007; Ryan et al., 2005; Lowenthal and Kumar, 2004) and at sites in China (U.S. EPA, 2019, section 13.2.3.3). To resolve these biases, a *revised IMPROVE equation*, shown in Equation D-2 in Appendix D, was developed (Pitchford et al., 2007) that divides PM components into smaller and larger sizes of particles in  $PM_{2.5}$ , with separate mass scattering efficiencies and hygroscopic growth functions for each size category. The revised IMPROVE equation was described in detail in the 2009 ISA (U.S. EPA, 2009) and it both reduced bias at the lowest and highest scattering values and improved the accuracy of the calculated light  $b_{ext}$ .

---

<sup>8</sup> The algorithm is referred to as the IMPROVE algorithm as it was developed specifically to use monitoring data generated at IMPROVE network sites and with equipment specifically designed to support the IMPROVE program and was evaluated using IMPROVE optical measurements at the subset of monitoring sites that make those measurements (Malm et al., 1994).

However, poorer precision was observed with the revised IMPROVE equation compared to the original IMPROVE equation (U.S. EPA, 2009).<sup>9</sup>

Since the time of the last review, Lowenthal and Kumar (2016) have tested and evaluated a number of modifications to the revised IMPROVE equation based on evaluations of monitoring data from remote IMPROVE sites. In these locations, they observed that the multiplier to estimate the concentration of organic matter, [OM], from the concentration of organic carbon, [OC], was closer to 2.1 than the value of 1.8 used in the revised IMPROVE equation.<sup>10</sup> They also observed that water soluble organic matter absorbs water as a function of relative humidity, which is not accounted for in either the original or revised IMPROVE equations and was therefore underestimated in these equations. They further suggested that light scattering by sulfate was overestimated because the assumption that all sulfate is fully neutralized ammonium sulfate is not always true (U.S. EPA, 2019, section 13.2.3.3). Modifications based on these points are reflected in Equation D-3 in Appendix D.

In summary, rather than altering our understanding from the previous review, we continue to recognize that direct measurements are better at characterizing light extinction than estimating light extinction with an algorithm. However, in the absence of advances in the monitoring methods and/or network for directly measuring light extinction, the use of the IMPROVE equation for estimating light extinction continues to be supported by the evidence, with some new refinements to the inputs of the IMPROVE equation. Accordingly, as in the last review, the current review focuses on calculated light extinction when quantifying visibility impairment resulting from recent concentrations of PM in ambient air.

- **What does the available information indicate with regard to factors that influence light extinction and visibility, as well as variation in these factors and resulting light extinction across the U.S.?**

The ISA provides a comprehensive discussion of the spatial and temporal patterns of PM<sub>2.5</sub> composition and its contribution to light extinction from IMPROVE and CSN monitoring

---

<sup>9</sup> In the most recent IMPROVE report, a combination of the original and revised IMPROVE equations (the *modified original IMPROVE equation*) was used (Hand et al., 2011). This equation uses the sea salt term of the revised equation but does not subdivide the components into two size classes. Further, it uses a factor of 1.8 to estimate organic matter from organic carbon concentrations and also replaces the constant value of 10 Mm<sup>-1</sup> used for Rayleigh scattering in the original and revised equations with a site-specific term based on elevation and mean temperature.

<sup>10</sup> In areas near sources, PM is often less oxygenated, and therefore, in these locations, much of the organic PM mass is present as OC (Jimenez et al., 2009). In areas further away from PM sources, organic PM mass is often more oxygenated as a result of photochemical activity and interactions with other PM and gaseous components in the atmosphere (Jimenez et al., 2009). Under these conditions, the multiplier to convert OC to OM may be higher than in locations with less aged organic PM.

sites, which are mostly rural and urban, respectively.<sup>11</sup> The data from these sites for the periods of 2005-2008 and 2011-2014 were used in the ISA to identify differences in species contributing to light extinction in urban and rural areas by region and season. This is an expansion over the analysis in the 2009 ISA, in that the measurements at that time were primarily based measurements from monitors located in rural areas and at remote sites (U.S. EPA, 2019, section 13.2.4.1, Figures 13-1 through 13-14).

Focusing on the more recent time period of 2011-2014, some major differences in estimated light extinction are apparent among regions of the U.S. Annual average calculated  $b_{ext}$  was considerably greater in the East and Midwest than in the Southwest. Based on IMPROVE data, annual average  $b_{ext}$  was greater than  $40 \text{ Mm}^{-1}$  in the Southeast, East Coast, Mid-South, Central Great Plains, and Appalachian regions, with the highest annual average  $b_{ext}$  (greater than  $50 \text{ Mm}^{-1}$ ) in the Ohio River Valley,<sup>12</sup> while annual average  $b_{ext}$  was below  $40 \text{ Mm}^{-1}$  for all Western IMPROVE regions. Annual average  $b_{ext}$  values were also generally higher in the East than the West based on CSN data, although the highest annual average  $b_{ext}$  was in the Sacramento/San Joaquin Valley and Los Angeles areas (U.S. EPA, 2019, section 13.2.4.1, Figure 13-1, Figure 13-3, Figure 13-5).

Components of  $\text{PM}_{2.5}$  contributing to light extinction vary regionally. For example, in the Eastern regions, ammonium sulfate accounted for approximately 35 to 60% of the annual average  $b_{ext}$ , with the greatest contributions typically occurring in the summer. The second greatest contribution to light extinction came from particulate organic matter (POM), ranging from about 20 to 30% of annual average  $b_{ext}$  with less seasonal variation than ammonium sulfate. Ammonium nitrate also contributed approximately 10% to 35% of annual average  $b_{ext}$ , with much higher concentrations in the winter than in the summer (U.S. EPA, 2019, section 13.2.4.1). In the Northwest, POM was the largest contributor to annual average  $b_{ext}$ , up to 70%, in most urban and rural regions with the greatest contributions in the fall. This seasonal contribution of POM may be related to wildfires. A few exceptions included Boise and sites in North Dakota, where ammonium nitrate was the greatest contributor, and sites in the Alaska IMPROVE region, where ammonium sulfate was the greatest contributor (U.S. EPA, 2019, section 13.2.4.1). In the Southwest, based on IMPROVE data, ammonium sulfate or POM were generally the greatest contributors to annual average  $b_{ext}$ , with nearly equivalent contributions in several regions. Based on CSN data, ammonium nitrate was often the greatest contributor, with especially high  $b_{ext}$  contributions in the winter. While  $\text{PM}_{10-2.5}$  mass scattering was relatively small in the eastern and

---

<sup>11</sup> Monitors were grouped into 28 IMPROVE regions and 31 CSN regions based on site location and PM concentrations for major species. For comparison purposes, and where possible, CSN regions were defined similarly to those for the IMPROVE network (Hand et al., 2011; U.S. EPA, 2019, section 13.2.4.1).

<sup>12</sup> A  $b_{ext}$  value of  $40 \text{ Mm}^{-1}$  corresponds to a visual range of about 100 km.

northwestern U.S., in the Southwest, PM<sub>10-2.5</sub> mass scattering contributed to more than 20% of light extinction (U.S. EPA, 2019, section 13.2.4.1).

Differences also exist between the urban CSN and the mainly rural IMPROVE data. Light extinction is generally higher in CSN regions than the geographically corresponding IMPROVE regions. Annual average  $b_{ext}$  was greater than 50 Mm<sup>-1</sup> in 11 CSN regions, compared to only one IMPROVE region, and was greater than 20 Mm<sup>-1</sup> in all CSN regions, compared to just over half of the IMPROVE regions. Light absorbing carbon was the greatest contributor to light extinction in several Western CSN regions but was not a large contributor in any of the IMPROVE regions (U.S. EPA, 2019, Figure 13-11). Ammonium nitrate also accounted for more light extinction in the CSN regions, while it was only a top contributor to  $b_{ext}$  in one IMPROVE region (U.S. EPA, 2019, section 13.2.4.1).

From the 2005-2008 time period to the 2011-2014 time period, the annual average  $b_{ext}$  in most CSN regions in the Eastern U.S. decreased by more than 20 Mm<sup>-1</sup>. This corresponds to an improvement in average visual range in most Eastern U.S. regions of more than 6 Mm<sup>-1</sup> (or 15 km) from 2005-2008 to 2011-2014. Additionally, the contribution of ammonium sulfate to light extinction has also changed over this period. Due to decreased atmospheric sulfate concentrations, the impact on visibility impairment is evident with a smaller fraction of the total  $b_{ext}$  accounted for by ammonium sulfate in 2011-2014 compared to 2005-2008 (U.S. EPA, 2019, section 13.2.4.1).

In summary, the spatial and temporal analysis of PM monitoring network data in the ISA emphasizes that the extent of light extinction by PM<sub>2.5</sub> depends on PM<sub>2.5</sub> composition and relative humidity. Regional differences in PM<sub>2.5</sub> composition greatly influence light extinction. Changes in PM<sub>2.5</sub> composition over time can also affect light extinction based on concentrations of specific PM components in ambient air.

- **To what extent are new studies available that might inform judgments about the potential adversity to public welfare of PM-attributable visibility impairment and the nature of the relationship between PM-attributable visibility impairment and public perceptions of such impairment?**

In the last review, visibility preference studies were available from four areas in North America,<sup>13</sup> as described in section 5.1.1 above. Study participants were queried regarding multiple images that, depending on the study, were either photographs of the same location and scenery that had been taken on different days on which measured extinction data were available

---

<sup>13</sup> As noted above, preference studies were available in four urban areas in the last review: Denver, Colorado (Ely et al., 1991, Pryor, 1996), Vancouver, British Columbia, Canada (Pryor, 1996), Phoenix, Arizona (BBC Research & Consulting, 2003), and Washington, DC (Abt Associates, 2001; Smith and Howell, 2009). More details about these studies are available in Appendix D.

or digitized photographs onto which a uniform “haze” had been superimposed. Results of these studies indicated a wide range of judgments on what study participants considered to be acceptable visibility across the different study areas, depending on the setting depicted in each photograph. As a part of the 2010 UFVA, each study was evaluated separately, and figures were developed to display the percentage of participants that rated the visual air quality depicted as “acceptable” (U.S. EPA, 2010). Figure 5-2 represents a graphical summary of the results of the studies in the four cities and identifies a range encompassing the PM<sub>2.5</sub> visibility index values from images that were judged to be acceptable by at least 50% of study participants across all four of the urban preference studies (U.S. EPA, 2010, p. 4-24).<sup>14</sup> As shown in Figure 5-2, much lower visibility (considerably more haze resulting in higher values of light extinction) was considered acceptable in Washington, D.C. than was in Denver. The median judgment for the study groups in the two areas differed by 9.2 dv (which roughly corresponds to about 30 µg/m<sup>3</sup> of PM) (U.S. EPA, 2010).

**Figure 5-2. Relationship of viewer acceptability ratings to light extinction.** (Source: U.S. EPA, 2011, Figure 4-2; U.S. EPA, 2010, Figure 2-16)

<sup>14</sup> Figure 5-2 shows the results of a logistical regression analysis using a logit model of the acceptable or unacceptable ratings from participants of the studies. The logit model is a generalized linear model used for binomial regression analysis which fits explanatory data about binary outcomes (in this case, a person rating an image as acceptable or unacceptable) to a logistic function curve. A detailed description is available in Appendix J of the 2010 UFVA (U.S. EPA, 2010).

Since the time of the last review, no new visibility preference studies have been conducted in the U.S. Outside of the U.S., a visibility preference study was carried out in Beijing, China (Fajardo et al., 2013). This study found a higher range of acceptable visibility impairment among participants than was found in preference studies previously conducted in the U.S. This finding may be related to the common occurrence of higher PM<sub>2.5</sub> concentrations in Beijing (with associated visibility impairment) than is typical in the U.S. (U.S. EPA, 2019, section 13.2.5). Similarly, there is little newly available information regarding acceptable levels of visibility impairment in the U.S.

- **To what extent have important uncertainties in the evidence from the last review been addressed, and have new uncertainties emerged?**

While some refinements have been made to the IMPROVE equation to better estimate light extinction since the last review, there has been no expansion of monitoring efforts for direct measurement of light extinction. At the time of the last review, it was noted that a PM<sub>2.5</sub> light extinction monitoring program could help with characterizing visibility conditions and the relationships between PM component concentrations and light extinction.

Little to no new research is available that helps to expand our understanding of visibility preferences or our characterization of visibility conditions. Uncertainties and limitations consistent with those identified in the last review persist in this review.

- Given the potential for people to have different preferences based on the visibility they are used to based on conditions that they commonly encounter, and the potential for them to also have different preferences for different types of scenes, the currently available preference studies may not capture the range of preferences of people in the U.S.
- The available preference studies were conducted 15 to 30 years ago and may not reflect the visibility preferences of the U.S. population today. Given that air quality has improved over the last several decades, the available studies may not reflect current preferences of people in the U.S.
- The available preference studies have used different methods to evaluate what level of visibility impairment is acceptable. Variability in study methodology may influence an individual's response as to what level of visibility impairment is deemed acceptable, and thereby influence the results of the study.
- Many factors that are not captured by the methods used in the currently available preference studies may influence people's judgments on acceptable visibility. For example, an individual's perception of an acceptable level of visibility impairment could be influenced by the duration of visibility impairment experienced, the time of day during which light extinction is greatest, and the frequency of episodes of visibility impairment, as well as the intensity of the visibility impairment (i.e., the focus of the available studies).

Overall, the body of evidence regarding visibility effects remains largely unchanged since the time of the last review. While one new study provides refinements to the methods for estimating light extinction, uncertainties and limitations in the scientific evidence during the last review remain.

#### **5.2.1.2 Quantitative Assessment-Based Considerations**

Beyond our consideration of the scientific evidence, discussed in section 5.2.1.1 above, we have also considered quantitative analyses of PM air quality and visibility impairment with regard to the extent they could inform conclusions on the adequacy of the public welfare protection provided by the current secondary PM standards. In the last review, quantitative analyses focused on daily visibility impairment, given the short-term nature of PM-related visibility effects. Such quantitative analyses conducted as part of the last review informed the decision on the secondary standards in that review (U.S. EPA, 2010, U.S. EPA, 2011; 78 FR 3189-3192, January 15, 2013). The information newly available in this review includes an updated equation for estimating light extinction, summarized in section 5.2.1.1 above, as well as more recent air monitoring data, that together allow for development of an updated assessment with the potential to substantially add to our understanding of PM-related visibility impairment. Thus, we have conducted updated analyses for this review based on the currently available technical information, tools, and methods.

- **How much visibility impairment is estimated to occur in areas that meet the current secondary PM standards? What are the factors contributing to the estimates in areas with higher values?**

Consistent with the analyses conducted in the last review, we have conducted analyses examining the relationship between PM mass concentrations and calculated light extinction using the 3-year design values<sup>15</sup> for the current secondary standards and a 3-year average visibility metric based on light extinction estimated using IMPROVE equations.<sup>16</sup> These analyses are intended to inform our understanding of visibility impairment in the U.S. under recent air quality conditions, particularly those conditions that meet the current standards, and the relative influence of various factors on light extinction. Given the relationship of visibility with short-term PM, we focus particularly on the short-term PM standards.

---

<sup>15</sup> A design value is a statistic that summarizes the air quality data for a given area in terms of the indicator, averaging time, and form of the standard. Design values can be compared to the level of the standard and are typically used to designate areas as meeting or not meeting the standard and assess progress towards meeting the NAAQS.

<sup>16</sup> This is the 3-year visibility metric that was used to evaluate visibility impairment in the last review. Given that there has been almost no new research since the time of the last review to better inform our understanding of visibility preferences in the U.S., there is no new information available to inform selection of a visibility metric for evaluating visibility impairment in the current review different from the one identified in the last review.

Given that visibility-related effects are often associated with short-term PM concentrations, and recognizing the relatively larger role of PM<sub>2.5</sub> and its components in light extinction and as inputs to the IMPROVE equation, we have given somewhat more attention to consideration of the 24-hour PM<sub>2.5</sub> standard. Analyses were conducted using three versions of the IMPROVE equation (Equations D-1 through D-3 in Appendix D) to estimate light extinction to better understand the influence of variability in inputs across the three equations. This analysis included 67 monitoring sites that are geographically distributed across the U.S. in both urban and rural areas (see Figure D-1 in Appendix D). These sites are those that have a valid 24-hour PM<sub>2.5</sub> design value for the 2015-2017 period and met strict criteria for PM species for this analysis.<sup>17</sup> We first present results for these 67 sites using the original IMPROVE equation, with modifications to the equation consistent with those made in evaluating light extinction in the last review (described in detail in section D.1 of Appendix D). We then present results for these 67 sites with light extinction calculated using the Lowenthal and Kumar (2016) IMPROVE equation described in section 5.2.1.1 above. For a subset of 20 of the 67 monitoring sites where PM<sub>10</sub> data were available and met completeness criteria for this analysis, we then present results of a second analysis that included the coarse fraction as an input to the IMPROVE equations for calculating light extinction to better characterize the influence of coarse PM on light extinction.

In considering the relationship between the 24-hour PM<sub>2.5</sub> mass-based design value and the 3-year visibility metric using recent air quality data, we first examine the relationship using the original IMPROVE equation, consistent with the methods used in the last review (Kelly et al., 2012b; 78 FR 3201, January 15, 2013; Appendix D). In those areas that meet the current 24-hour PM<sub>2.5</sub> standard, all sites have light extinction estimates at or below 27 dv (Figure 5-3; 78 FR 3218, January 15, 2013). This is also true for the one location that exceeds the current 24-hour PM<sub>2.5</sub> standard (Figure 5-3). These findings are consistent with the findings of the analysis in the last review that used the same IMPROVE equation with data from 102 sites with data from 2008-2010. This indicates similar findings from this analysis as was the case with the similar analysis in the last review, i.e., the updated quantitative analysis shows that the 3-year visibility metric was no higher than 30 dv<sup>18</sup> at sites meeting the current secondary PM standards, and at

---

<sup>17</sup> For this analysis, completeness criteria for speciated PM data at these sites included having all 12 quarters in the 2015-2017 period with at least 11 days in each quarter with a valid PM<sub>2.5</sub> mass, sulfate, nitrate, organic carbon, elemental carbon, sea salt (chlorine or chloride), and fine soil (aluminum, silica, calcium, iron, and titanium) measurement.

<sup>18</sup> For comparison purposes in these air quality analyses, we use a 3-year visibility metric with a level of 30 dv, which is the highest level of visibility impairment judged to be acceptable by at least 50 percent of the participants in the preference studies that were available at the time of the last review (78 FR 3191, January 15, 2013).

most such sites the 3-year visibility index values are much lower (e.g., an average of 20 dv across the 67 sites).

**Figure 5-3. Comparison of 90<sup>th</sup> percentile of daily light extinction, averaged over three years, and 98<sup>th</sup> percentile of daily PM<sub>2.5</sub> concentrations, averaged over three years, for 2015-2017 using the original IMPROVE equation.** (Note: Dashed lines indicate the level of current 24-hour PM<sub>2.5</sub> standard (35 µg/m<sup>3</sup>) and the target level of protection identified for the 3-year visibility metric (30 dv).)

When light extinction was calculated using the refined equation from Lowenthal and Kumar (2016), the resulting 3-year visibility metrics are slightly higher at all sites compared to light extinction estimates calculated using the original IMPROVE equation (Figure 5-4). As noted in section 5.2.1.1, this version of the IMPROVE equation uses a multiplier of 2.1 to convert the measured OC to OM for input into the equation and also accounts for water absorption by water soluble organic matter as a function of relative humidity, likely contributing to the slightly higher estimates of light extinction. As noted in section 5.2.1.1, the Lowenthal and Kumar (2016) refinements to the IMPROVE equation are based on evaluations of monitoring data from remote IMPROVE sites. More remote areas tend to have more aged organic particles than urban areas, and these adjustments to the IMPROVE equation account for the higher concentration of organic matter as a result of more aged organic particles at these sites. It is

important to note that, since the Lowenthal and Kumar (2016) refinements to the IMPROVE equation likely result in one of the higher estimates of light extinction, this equation may overestimate light extinction in non-remote areas, including those urban areas in our analyses.

For those sites that meet the current 24-hour  $\text{PM}_{2.5}$  standard, the 3-year visibility metric is at or below 30 dv when light extinction is calculated using the Lowenthal and Kumar (2016) equation, with the exception of one site in Fairbanks, Alaska. This site just meets the current 24-hour  $\text{PM}_{2.5}$  standard and has a 3-year visibility index value of 31 dv (compared to 27 dv when light extinction is calculated with the original IMPROVE equation) (see Table D-3 in Appendix D). The conditions at this site, however, may differ considerably from those under which the Lowenthal and Kumar (2016) IMPROVE equation, with 2.1 as the multiplier to estimate OM from OC, has been evaluated. Some of these differences, which include higher OC concentrations, with OC as a much higher fraction of OM, much lower temperatures, and the complete lack of sunlight for long periods, may affect the quantitative relationships of OC and OM with visibility (e.g., Hand et al., 2012; Hand et al., 2013).

**Figure 5-4. Comparison of 90<sup>th</sup> percentile of daily light extinction, averaged over three years, and 98<sup>th</sup> percentile of daily  $\text{PM}_{2.5}$  concentrations, averaged over three years, for 2015-2017 using the Lowenthal and Kumar equation.** (Note: Dashed lines indicate the level of current 24-hour  $\text{PM}_{2.5}$  standard ( $35 \mu\text{g/m}^3$ ) and the target level of protection identified for the 3-year visibility metric (30 dv).)

In considering visibility impairment under recent air quality conditions, we recognize that the differences in the inputs to equations estimating light extinction can influence the resulting values. For example, given the varying chemical composition of emissions from different sources, the 2.1 multiplier in the Lowenthal and Kumar (2016) equation may not be appropriate for all source types. At the time of the last review, the EPA judged that a 1.6 multiplier for converting OC to OM was more appropriate, for the purposes of estimating visibility index at sites across the U.S., than the 1.4 or 1.8 multipliers used in the original and revised IMPROVE equations, respectively. A multiplier of 1.8 or 2.1 would account for the more aged and oxygenated organic PM that tends to be found in more remote regions than in urban regions, whereas a multiplier of 1.4 may underestimate the contribution of organic PM found in remote regions when estimating light extinction (78 FR 3206, January 15, 2013; U.S. EPA, 2012b, p. IV-5). The information and analyses available in the current review indicate that it may be appropriate to select inputs to the IMPROVE equation (e.g., the multiplier for OC to OM) on a regional basis rather than a national basis when calculating light extinction. This is especially true when comparing sites with localized PM sources (such as sites in urban or industrial areas) to sites with PM derived largely from biogenic precursor emissions (that contribute to widespread secondary organic aerosol formation), such as those in the southeastern U.S. We note, however, that conditions involving PM from such different sources have not been well studied in the context of applying a multiplier to estimate light extinction, contributing uncertainty to estimates of light extinction for such conditions.

At the time of the last review, the EPA noted that  $PM_{2.5}$  is the size fraction of PM responsible for most of the visibility impairment in urban areas (77 FR 38980, June 29, 2012). Data available at the time of the last review suggested that, generally,  $PM_{10-2.5}$  was a minor contributor to visibility impairment most of the time (U.S. EPA, 2010) although the coarse fraction may be a major contributor in some areas in the desert southwestern region of the U.S. Moreover, at the time of the last review, there were few data available from  $PM_{10-2.5}$  monitors to quantify the contribution of coarse PM to calculated light extinction. Since that time, an expansion in  $PM_{10-2.5}$  monitoring efforts has increased the availability of data for use in estimating light extinction with both  $PM_{2.5}$  and  $PM_{10-2.5}$  concentrations included as inputs in the equations. Collocated  $PM_{10-2.5}$  monitoring data were available at 20 of the 67  $PM_{2.5}$  sites (see Appendix D) for 2015-2017. Thus, the analysis in this review addressed light extinction estimated with coarse and fine PM at sites where feasible. All 20 of these sites met the 24-hour  $PM_{2.5}$  standard and 24-hour  $PM_{10}$  standard, and they all had 3-year visibility metrics at or below 30 dv when light extinction was calculated with and without the coarse fraction for any of the three versions of the IMPROVE equation. Generally, the contribution of the coarse fraction to

light extinction at these sites is minimal, contributing less than 1 dv to the 3-year visibility metric. However, we note that in our analysis, none of the locations included areas that would be expected to have greater concentrations of coarse PM, such as the southwest. In such locations, if PM<sub>10</sub> and PM<sub>10-2.5</sub> data were available, the coarse fraction may be a more important contributor to light extinction and visibility impairment than in those locations with lower concentrations of coarse PM. These results are consistent with those in the analyses in the ISA, which found that mass scattering from PM<sub>10-2.5</sub> was relatively small (less than 10%) in the eastern and northwestern U.S., whereas mass scattering was much larger in the Southwest (more than 20%) particularly in southern Arizona and New Mexico (U.S. EPA, 2019, section 13.2.4.1, p. 13-36).

In summary, the findings of these updated quantitative analyses are generally consistent with those in the last review. The 3-year visibility metric was generally below 25 dv in most areas that meet the current 24-hour PM<sub>2.5</sub> standard, with one location slightly above 30 dv, rounding to 31 dv. Small differences in the 3-year visibility metric were observed between the variations of the IMPROVE equation, which may suggest that it may be more appropriate to use one version over another in different regions of the U.S. based on PM characteristics such as particle size and composition to more accurately estimate light extinction. There was also very little difference in estimates of light extinction when the coarse fraction was included in the equation, although this may be more important in areas that have a higher concentration of coarse PM than those included in this analysis.

## 5.2.2 Non-Visibility Effects

### 5.2.2.1 Evidence-Based Considerations

In considering the available evidence for non-visibility welfare effects attributable to PM as presented in the ISA, this section poses the following policy-relevant questions:

- **To what extent has new scientific evidence improved our understanding of the nature and magnitude of non-visibility welfare effects of PM in ambient air, including the variability associated with such effects? To what extent have important uncertainties in the evidence from the last review been addressed, and have new uncertainties emerged?**

We address these questions for PM and climate effects (section 5.2.2.1.1) and materials effects (section 5.2.2.1.2) below.

#### 5.2.2.1.1 Climate Effects

In considering the available evidence of climate effects attributable to PM, this section poses the following policy-relevant question:

- **To what extent is new information available that changes or enhances our understanding of the climate impacts of PM-related aerosols, particularly regarding**

**a quantitative relationship between PM concentrations and effects on climate (e.g., through radiative forcing)?**

In the last review, the 2009 PM ISA concluded that there was “sufficient evidence to determine a causal relationship between PM and climate effects – specifically on the radiative forcing of the climate system, including both direct effects of PM on radiative forcing and indirect effects that involve cloud feedbacks that influence precipitation formation and cloud lifetimes” (U.S. EPA, 2009, section 9.3.10).<sup>19</sup> Since the last review, climate impacts have been extensively studied and the ISA concludes that “overall the evidence is sufficient to conclude that a causal relationship exists between PM and climate effects” (U.S. EPA, 2019, section 13.3.9). Recent research reinforces and strengthens the evidence evaluated in the 2009 ISA. New evidence provides greater specificity about the details of these radiative forcing effects and increased understanding of additional climate impacts driven by PM radiative effects. The Intergovernmental Panel on Climate Change (IPCC) assesses the role of anthropogenic activity in past and future climate change. In the last review, the 2009 ISA relied heavily on the Fourth IPCC Assessment Report (AR4); since that time the IPCC has issued an updated report. The Fifth IPCC Assessment Report (AR5; IPCC, 2013) reports on the key scientific advances in understanding the climate effects of PM since AR4. The ISA draws substantially upon AR5 in summarizing these effects.

Atmospheric PM has the potential to affect climate in multiple ways, including absorbing and scattering of incoming solar radiation, alterations in terrestrial radiation, effects on the hydrological cycle, and changes in cloud properties (U.S. EPA, 2019, section 13.3.1). Atmospheric PM interacts with incoming solar radiation. Many species of PM (e.g., sulfate and nitrate) efficiently scatter solar energy. By enhancing reflection of solar energy back to space, scattering PM exerts a cooling effect on the surface below. Certain species of PM such as black carbon (BC), brown carbon (BrC), or dust can also absorb incoming sunlight. A recent study found that whether absorbing PM warms or cools the underlying surface depends on several factors, including the altitude of the PM layer relative to cloud cover and the albedo of the surface (Ban-Weiss et al., 2014). PM also perturbs incoming solar energy by influencing cloud cover and cloud lifetime. For example, PM provides nuclei upon which water vapor condenses, forming cloud droplets. Finally, absorbing PM deposited on snow and ice can diminish surface albedo and lead to regional warming (U.S. EPA, 2019, section 13.3.2).

---

<sup>19</sup> Radiative forcing (RF) for a given atmospheric constituent is defined as the perturbation in net radiative flux, at the tropopause (or the top of the atmosphere) caused by that constituent, in watts per square meter ( $\text{Wm}^{-2}$ ), after allowing for temperatures in the stratosphere to adjust to the perturbation but holding all other climate responses constant, including surface and tropospheric temperatures (Fiore et al., 2015, Myhre et al., 2013). A positive forcing indicates net energy trapped in the Earth system and suggests warming of the Earth’s surface, whereas a negative forcing indicates net loss of energy and suggests cooling (U.S. EPA, 2019, section 13.3.2.2).

PM has direct and indirect effects on climate processes. PM interactions with solar radiation through scattering and absorption, collectively referred to as aerosol-radiation interactions (ARI), are also known as the direct effects of PM on climate, as opposed to the indirect effects that involve aerosol-cloud interactions (ACI). The direct effects of PM on climate result primarily from particles scattering light away from Earth and sending a fraction of solar energy back into space, decreasing the transmission of visible radiation to the surface of the Earth and resulting in a decrease in the heating rate of the surface and the lower atmosphere. The IPCC AR5, taking into account both model simulations and satellite observations, reports a radiative forcing from aerosol-radiation interactions (RFari) from anthropogenic PM of  $-0.35 \pm 0.5$  watts per square meter ( $\text{Wm}^{-2}$ ) (Boucher, 2013), which is slightly reduced compared to AR4. Estimates of effective radiative forcing<sup>20</sup> from aerosol-radiation interactions (ERFari), which include the rapid feedback effects of temperature and cloud cover, rely mainly on model simulations, as this forcing is complex and difficult to observe (U.S. EPA, 2019, section 13.3.4.1). The IPCC AR5 best estimate for ERFari is  $-0.45 \pm 0.5 \text{ Wm}^{-2}$ , which reflects this uncertainty (Boucher, 2013).

By providing cloud condensation nuclei, PM increases cloud droplet number, thereby increasing cloud droplet surface area and albedo (Twomey, 1977). The climate effects of these perturbations are more difficult to quantify than the direct effects of aerosols with RF but likely enhance the cooling influence of clouds by increasing cloud reflectivity (traditionally referred to as the first indirect effect) and lengthening cloud lifetime (the second indirect effect). These effects are reported as the radiative forcing from aerosol-cloud interactions (RFaci) and the effective radiative forcing from aerosol-cloud interactions (ERFaci) (U.S. EPA, 2019, section 13.3.3.2). IPCC AR5 estimates ERFaci at  $-0.45 \text{ Wm}^{-2}$ , with a 90% confidence interval of  $-1.2$  to  $0 \text{ Wm}^{-2}$  (U.S. EPA, 2019, section 13.3.4.2).<sup>21</sup> Studies have also calculated the combined effective radiative forcing from aerosol-radiation and aerosol-cloud interactions (ERFari+aci) (U.S. EPA, 2019, section 13.3.4.3). IPCC AR5 reports a best estimate of ERFari+aci of  $-0.90$  ( $-1.9$  to  $-0.1$ )  $\text{Wm}^{-2}$ , consistent with these estimates (Boucher, 2013).

PM can also strongly reflect incoming solar radiation in areas of high albedo, such as snow- and ice-covered surfaces. The transport and subsequent deposition of absorbing PM such as BC to snow- and ice-covered regions can decrease the local surface albedo, leading to surface

---

<sup>20</sup> Effective radiative forcing (ERF), new in the IPCC AR5, takes into account not just the instantaneous forcing but also a set of climate feedbacks, involving atmospheric temperature, cloud cover, and water vapor, that occur naturally in response to the initial radiative perturbation (U.S. EPA, 2019, section 13.3.2.2).

<sup>21</sup> While the ISA includes estimates of RFaci and ERFaci from a number of studies (U.S. EPA, 2019, sections 13.3.4.2, 13.3.4.3, 13.3.3.3), this PA focuses on the single best estimate with a range of uncertainty, as reported in IPCC AR5 (Boucher, 2013).

heating. The absorbed energy can then melt the snow and ice cover and further depress the albedo, resulting in a positive feedback loop (U.S. EPA, 2019, section 13.3.3.3; Bond et al., 2013; U.S. EPA, 2012a). Deposition of absorbing PM, such as BC, may also affect surface temperatures over glacial regions (U.S. EPA, 2019, section 13.3.3.3). The IPCC AR5 best estimate of RF from the albedo effect is  $+0.04 \text{ Wm}^{-2}$ , with an uncertainty range of  $+0.02$  to  $+0.09 \text{ Wm}^{-2}$  (Boucher, 2013).

While research on PM-related effects on climate has expanded since the last review, there are still significant uncertainties associated with the accurate measurement of PM contributions to the direct and indirect effects of PM on climate.

- **To what extent does the currently available information provide evidence of a quantitative relationship between specific PM constituents (i.e., BC, OC, sulfate) and climate-related effects?**

Since the last review, a number of new studies have examined the individual climate effects associated with key PM components, including sulfate, nitrate, OC, BC, and dust, along with updated quantitative estimates of the radiative forcing associated with the individual species.

Sulfate particles form through oxidation of  $\text{SO}_2$  by OH in the gas phase and in the aqueous phase by a number of pathways, including in particular those involving ozone and  $\text{H}_2\text{O}_2$  (U.S. EPA, 2019, section 13.3.5.1). The main source of anthropogenic sulfate is from coal-fired power plants, and global trends in the anthropogenic  $\text{SO}_2$  emissions are estimated to have increased dramatically during the 20<sup>th</sup> and early 21<sup>st</sup> centuries, although the recent implementation of more stringent air pollution controls on sources has led to a reversal in such trends in many places (U.S. EPA, 2019, section 13.3.5.1). Sulfate particles are highly reflective. Consistent with other recent estimates, on a global scale, the IPCC AR5 estimates that sulfate contributes more than other PM types to RF, with  $\text{RF}_{\text{ari}}$  of  $-0.4$  ( $-0.6$  to  $-0.2$ )  $\text{Wm}^{-2}$ , where the 5% and 95% uncertainty range is represented by the numbers in the parentheses (Myhre et al., 2013). This uncertainty range indicates the challenges associated with estimating  $\text{SO}_2$  from sources in developing regions and estimating the lifetime of sulfate against wet deposition. Sulfate is also a major contributor to the influence of PM on clouds (Takemura, 2012). A total effective radiative forcing ( $\text{ERF}_{\text{ari+aci}}$ ) for anthropogenic sulfate has been estimated to be nearly  $-1.0 \text{ Wm}^{-2}$  (Zelinka et al., 2014, Adams et al., 2001).

Nitrate particles form through the oxidation of nitrogen oxides and occur mainly in the form of ammonium nitrate. Ammonium preferentially associates with sulfate rather than nitrate, leading to formation of ammonium sulfate at the expense of ammonium nitrate (Adams et al., 2001). As anthropogenic emissions of  $\text{SO}_2$  decline, more ammonium will be available to react with nitrate, potentially leading to future increases in ammonium nitrate particles in the

atmosphere (U.S. EPA, 2019, section 13.3.5.2; Hauglustaine et al., 2014; Lee et al., 2013; Shindell et al., 2013). Warmer global temperatures, however, may decrease nitrate abundance given that it is highly volatile at higher temperatures (Tai et al., 2010). The IPCC AR5 estimates RFari of nitrate of  $-0.11$  ( $-0.3$  to  $-0.03$ )  $\text{Wm}^{-2}$  (Boucher, 2013), which is one-fourth of the RFari of sulfate.

Primary organic carbonaceous PM, including BrC, are emitted from wildfires, agricultural fires, and fossil fuel and biofuel combustion. Secondary organic aerosols (SOA) form when anthropogenic or biogenic nonmethane hydrocarbons are oxidized in the atmosphere, leading to less volatile products that may partition into PM (U.S. EPA, 2019, section 13.3.5.3). Organic particles are generally reflective, but in the case of BrC, a portion is significantly absorbing at shorter wavelengths ( $<400$  nm). The IPCC AR5 estimates an RFari for primary organic PM from fossil fuel combustion and biofuel use of  $-0.09$  ( $-0.16$  to  $-0.03$ )  $\text{Wm}^{-2}$  and an RFari estimate for SOA from these sources of  $-0.03$  ( $-0.27$  to  $+0.20$ )  $\text{Wm}^{-2}$  (Myhre et al., 2013). The wide range in these estimates, including inconsistent signs for forcing, reflect uncertainties in the optical properties of organic PM and its atmospheric budgets, including the production pathways of anthropogenic SOA (Scott et al., 2014; Myhre et al., 2013; McNeill et al., 2012; Heald et al., 2010). The IPCC AR5 also estimates an RFari of  $-0.2$   $\text{Wm}^{-2}$  for primary organic PM arising from biomass burning (Boucher, 2013).

Black carbon (BC) particles occur as a result of inefficient combustion of carbon-containing fuels. Like directly emitted organic PM, BC is emitted from biofuel and fossil fuel combustion and by biomass burning. BC is absorbing at all wavelengths and likely has a large impact on the Earth's energy budget (Bond et al., 2013). The IPCC AR5 estimates a RFari from anthropogenic fossil fuel and biofuel use of  $+0.4$  ( $+0.5$  to  $+0.8$ )  $\text{Wm}^{-2}$  (Myhre et al., 2013). Biomass burning contributes an additional  $+0.2$  ( $+0.03$  to  $+0.4$ )  $\text{Wm}^{-2}$  to BC RFari, while the albedo effect of BC on snow and ice adds another  $+0.04$  ( $+0.02$  to  $+0.09$ )  $\text{Wm}^{-2}$  (Myhre et al., 2013; U.S. EPA, 2019, section 13.3.5.4, section 13.3.4.4).

Dust, or mineral dust, is mobilized from dry or disturbed soils as a result of both meteorological and anthropogenic activities. Dust has traditionally been classified as scattering, but a recent study found that dust may be substantially coarser than currently represented in climate models, and thus more light-absorbing (Kok et al., 2017). The IPCC AR5 estimates RFari as  $-0.1 \pm 0.2$   $\text{Wm}^{-2}$  (Boucher, 2013), although the results of the study by Kok et al. (2017) would suggest that in some regions dust may have led to warming, not cooling (U.S. EPA, 2019, section 13.3.5.5).

The new research available in this review expands upon the evidence available at the time of the last review. Consistent with the evidence available in the last review, the key PM

components, including sulfate, nitrate, OC, BC, and dust, that contribute to climate processes vary in their reflectivity, forcing efficiencies, and direction of forcing.

- **To what extent does newly available evidence change or improve our understanding of the spatial and temporal variation in climate responses to PM?**

Radiative forcing due to PM elicits a number of responses in the climate system that can lead to significant effects on weather and climate over a range of spatial and temporal scales, mediated by a number of feedbacks that link PM and climate. Since the last review, the evidence base has expanded with respect to the mechanisms of climate responses and feedbacks to PM radiative forcing, described below, although considerable uncertainties continue to exist. We focus our discussion primarily on the climate impacts in the U.S.

Unlike well-mixed, long-lived greenhouse gases in the atmosphere, PM has a very heterogeneous distribution across the Earth. As such, patterns of  $RF_{air}$  and  $RF_{surf}$  tend to correlate with PM loading, with the greatest forcings centralized over continental regions. The climate response is more complicated since the perturbation to one climate variable (e.g., temperature, cloud cover, precipitation) can lead to a cascade of effects on other variables. While the initial PM radiative forcing may be concentrated regionally, the eventual climate response can be much broader spatially or be concentrated in remote regions (U.S. EPA, 2019, section 13.3.6). The complex climate system interactions lead to variation among climate models, with some studies showing relatively close correlation between forcing and surface response temperatures (e.g., Leibenberger et al., 2012), while other studies show much less correlation (e.g., Levy et al., 2013). Many studies have examined observed trends in PM and temperature in the U.S. Climate models have suggested a range of factors which can influence large-scale meteorological processes and may affect temperature, including local feedback effects involving soil moisture and cloud cover, changes in the hygroscopicity of the PM, and interactions with clouds alone (U.S. EPA, 2019, section 13.3.7). While evidence in this review suggests that PM influenced temperature trends across the southern and eastern U.S. in the 20<sup>th</sup> century, uncertainties continue to exist and further research is needed to better characterize the effects of PM on regional climate in the U.S.

- **To what extent have important uncertainties identified in the last review been reduced and/or have new uncertainties emerged?**

Since 2009, significant progress has been made in evaluating PM-related climate effects and uncertainties. The IPCC AR5 states that “climate-relevant aerosol processes are better understood, and climate-relevant aerosol properties are better observed, than at the time of the AR4” (Boucher, 2013). However, significant uncertainties remain that make it difficult to

quantify the climate effects of PM. Such uncertainties include those related to our understanding of:

- The magnitude of PM radiative forcing and the portion of that associated with anthropogenic emissions;
- The contribution of regional differences in PM concentrations, and of individual components, to radiative forcing;
- The mechanisms of climate responses and feedbacks resulting from PM-related radiative forcing; and,
- The process by which PM interacts with clouds and how to represent such interactions in climate models.

While research has progressed significantly since the last review, substantial uncertainties still remain with respect to key processes linking PM and climate, because of the small scale of PM-relevant atmospheric processes compared to the resolution of state-of-the-art models, and because of the complex cascade of indirect impacts and feedbacks in the climate system that result from an initial PM-related radiative perturbation (U.S. EPA, 2019, section 13.3.9).

#### **5.2.2.1.2 Materials Effects**

In considering the available evidence on materials effects attributable to PM, this section poses the following policy-relevant question:

- **To what extent is new information available to link PM to materials effects, including degradation of surfaces, and deterioration of materials such as metal, stone, concrete and marble?**

In the last review, the 2009 ISA concluded that there was “a causal relationship between PM and effects on materials” (U.S. EPA, 2009, sections 2.5.4 and 9.5.4). Rather than altering our conclusions from the last review, the current evidence continues to support our prior conclusion regarding materials effects associated with PM deposition. Effects of deposited PM, particularly sulfates and nitrates,<sup>22</sup> to materials include both physical damage and impaired aesthetic qualities. Because of their electrolytic, hygroscopic, and acidic properties and their ability to sorb corrosive gases, particles contribute to materials damage by adding to the effects of natural weathering processes, by potentially promoting or accelerating the corrosion of metals, degradation of painted surfaces, deterioration of building materials, and weakening of material components. The majority of the newly available evidence on materials effects of PM are from

---

<sup>22</sup> In the case of materials effects, it is difficult to isolate the effects of gaseous and particulate N and S wet deposition so both will be considered along with other PM-related deposition effects on materials in this review of the PM NAAQS.

outside the U.S. on buildings and other items of cultural heritage; however, they provide limited new data for consideration in this review (U.S. EPA, 2019, section 13.4).

Materials damage from PM generally involves one or both of two processes: soiling and corrosion (U.S. EPA, 2019, section 13.4.2). Soiling and corrosion are complex, interdependent processes, typically beginning with deposition of atmospheric PM or SO<sub>2</sub> to exposed surfaces. Constituents of deposited PM can interact directly with materials or undergo further chemical and/or physical transformation to cause soiling, corrosion, and physical damage. Weathering, including exposure to moisture, ultraviolet (UV) radiation and temperature fluctuations, affects the rate and degree of damage (U.S. EPA, 2019, section 13.4.2).

Soiling is the result of PM accumulation on an object that alters its optical characteristics or appearance. These soiling effects can impact the aesthetic value of a structure or result in reversible or irreversible damage to the surface. The presence of air pollution can increase the frequency and duration of cleaning and can enhance biodeterioration processes on the surface of materials. For example, deposition of carbonaceous components of PM can lead to the formation of black crusts on surfaces, and the buildup of microbial biofilms<sup>23</sup> can discolor surfaces by trapping PM more efficiently (U.S. EPA, 2009, p. 9-195; U.S. EPA, 2019, section 13.4.2). The presence of PM may alter light transmission or change the reflectivity of a surface. Additionally, the organic or nutrient content of deposited PM may enhance microbial growth on surfaces.

Since the last review, very little new evidence has become available related to deposition of SO<sub>2</sub> to materials such as limestone, granite, and metal. Deposition of SO<sub>2</sub> onto limestone can transform the limestone into gypsum, resulting in a rougher surface, which allows for increased surface area for accumulation of deposited PM (Camuffo and Bernardi, 1993; U.S. EPA, 2019, section 13.4.2). Oxidation of deposited SO<sub>2</sub> that contributes to the transformation of limestone to gypsum can be enhanced by the formation of surface coatings from deposited carbonaceous PM (both elemental and organic carbon) (McAlister et al., 2008, Grossi et al., 2007). Ozga et al. (2011) characterized damage to two concrete buildings in Poland and Italy. Gypsum was the main damage product on surfaces of these buildings that were sheltered from rain runoff, while PM embedded in the concrete, particularly carbonaceous particles, were responsible for darkening of the building walls (Ozga et al., 2011).

Building on the evidence available in the 2009 ISA, research has progressed on the theoretical understanding of soiling of cultural heritage in a number of studies. Barca et al. (2010) developed and tested a new methodological approach for characterizing trace elements and heavy metals in black crusts on stone monuments to identify the origin of the chemicals and

---

<sup>23</sup> Microbial biofilms are communities of microorganisms, which may include bacteria, algae, fungi and lichens, that colonize an inert surface. Microbial biofilms can contribute to biodeterioration of materials via modification of the chemical environment.

the relationship between the concentrations of elements in the black crusts and local environmental conditions. Recent research has also used isotope tracers to distinguish between contributions from local sources versus atmospheric pollution to black crusts on historical monuments in France (Kloppmann et al., 2011). A study in Portugal found that biological activity played a major role in soiling, specifically in the development of colored layers and in the detachment process (de Oliveira et al., 2011). Another study found damage to cement renders, often used for restoration, consolidation, and decorative purposes on buildings, following exposure to sulfuric acid, resulting in the formation of gypsum (Lanzon and Garcia-Ruiz, 2010).

Corrosion of stone and the decay of stone building materials by acid deposition and sulfate salts were described in the 2009 ISA (U.S. EPA, 2009, section 9.5.3). Since that time, advances have been made on the quantification of degradation rates and further characterization of the factors that influence damage of stone materials (U.S. EPA, 2019, section 13.4.2). Decay rates of marble grave stones were found to be greater in heavily polluted areas compared to a relatively pristine area (Mooers et al., 2016). The time of wetness and the number of dissolution/crystallization cycles were identified as hazard indicators for stone materials, with greater hazard during the spring and fall when these indicators are relatively high (Casati et al., 2015).

A study examining the corrosion of steel as a function of PM composition and particle size found that changes in the composition of resulting rust gradually changed with particle size (Lau et al., 2008). In a study of damage to metal materials under in Hong Kong, which generally has much higher PM concentrations than those observed in the U.S., Liu et al. (2015) found that iron and steel were corroded by both PM and gaseous pollutants ( $\text{SO}_2$  and  $\text{NO}_2$ ), while copper and copper alloys were mainly corroded by gaseous pollutants ( $\text{SO}_2$  and  $\text{O}_3$ ) and aluminum and aluminum alloy corrosion was mainly attributed to PM and  $\text{NO}_2$ .

A number of studies have also found materials damage from PM components besides sulfate and black carbon and atmospheric gases besides  $\text{SO}_2$ . Studies have characterized impacts of nitrates,  $\text{NO}_x$ , and organic compounds on direct materials damage or on chemical reactions that enhance materials damage (U.S. EPA, 2019, section 13.4.2). Other studies have found that soiling of building materials can be attributed to enhanced biological processes and colonization, including the development and thickening of biofilms, resulting from the deposition of PM components and atmospheric gases (U.S. EPA, 2019, section 13.4.2).

Since the last review, other materials have been studied for damage attributable to PM, including glass and photovoltaic panels. Soiling of glass can impact its optical and thermal

properties, and can lead to increased cleaning costs and frequency. The development of haze<sup>24</sup> on modern glass has been measured and modeled, with a strong correlation between the size distribution of particles and the evolution of the mass deposited on the surface of the glass. Measurements showed that, under sheltered conditions, mass deposition accelerated regularly with time in areas closest to sources of PM (i.e., near roadways) and coarse mineral particles were more prevalent compared to other sites (Alfaro et al., 2012). Model predictions were found to correctly simulate the development of haze at site locations when compared with measurements (Alfaro et al., 2012).

Soiling of photovoltaic panels can lead to decreased energy efficiency. For example, soiling by carbonaceous PM decreased solar efficiency by nearly 38%, while soil particles reduced efficiency by almost 70% (Radonjic et al., 2017). The rate of photovoltaic power output can also be degraded by soiling and has been found to be related to the rate of dust accumulation. In five sites in the U.S. representing different meteorological and climatological conditions,<sup>25</sup> photovoltaic module power transmission was reduced by approximately 3% for every g/m<sup>2</sup> of PM deposited on the cover plate of the photovoltaic panel, independent of geographical location (Boyle et al., 2017). Another study found that photovoltaic module power output was reduced by 40% after 10 months of exposure without cleaning, although a number of anti-reflective coatings can generally mitigate power reduction resulting from dust deposition (Walwil et al., 2017). Energy efficiency can also be impacted by the soiling of building materials, such as light-colored marble panels on building exteriors, that are used to reflect a large portion of solar radiation for passive cooling and to counter the urban heat island effect. Exposure to acidic pollutants in urban environments have been found to reduce the solar reflectance of marble, decreasing the cooling effect (Rosso et al., 2016). Highly reflective roofs, or cool roofs, have been designed and constructed to increase reflectance from buildings in urban areas, to both decrease air conditioning needs and urban heat island effects, but these efforts can be impeded by soiling of materials used for constructing cool roofs. Methods have been developed for accelerating the aging process of roofing materials to better characterize the impact of soiling and natural weather on materials used in constructing cool roofs (Sleiman et al., 2014).

---

<sup>24</sup> In this discussion of non-visibility welfare effects (section 5.2.2), haze is used as it has been defined in the scientific literature on soiling of glass, i.e., the ratio of diffuse transmitted light to direct transmitted light (Lombardo et al., 2010). This differs from the definition of haze as used in the discussion of visibility welfare effects in section 5.2.1, where it is used as a qualitative description of the blockage of sunlight by dust, smoke, and pollution.

<sup>25</sup> Of the five sites studied, three were in rural, suburban, and urban areas representing a semi-arid environment (Front Range of Colorado), one site represented a hot and humid environment (Cocoa, Florida), and one represented a hot and arid environment (Albuquerque, New Mexico) (U.S. EPA, 2019, section 13.4.2; Boyle et al., 2017).

- **To what extent has new information emerged for quantifying material damage attributable to PM through dose-response relationships or damage functions? Are there studies linking perceptions of reduced aesthetic appeal of buildings and other objects to PM or wet deposition of N and S species?**

Some progress has been made since the last review in the development of dose-response relationships for soiling of building materials, although some key relationships remain poorly characterized. The first general dose-response relationships for soiling of materials were generated by measuring contrast reflectance of a soiled surface to the reflectance of the unsoiled substrate for different materials, including acrylic house paint, cedar siding, concrete, brick, limestone, asphalt shingles, and window glass with varying total suspended particulate (TSP) concentrations (Beloin and Haynie, 1975; U.S. EPA, 2019, section 13.4.3). Continued efforts to develop dose-response curves for soiling have led to some advancements for modern materials, but these relationships remain poorly characterized for limestone. A recent study quantified the dose-response relationships between  $PM_{10}$  and soiling for painted steel, white plastic, and polycarbonate filter material, but there was too much scatter in the data to produce a dose-response relationship for limestone (Watt et al., 2008). A dose-response relationship for silica-soda-lime window glass soiling by  $PM_{10}$ ,  $NO_2$ , and  $SO_2$  was quantified based on 31 different locations (Lombardo et al., 2010; U.S. EPA, 2019, section 13.4.3, Figure 13-32, Equation 13-8). The development of this dose-response relationship required several years of observation time and had inconsistent data reporting across the locations.

Since the last review, there has also been progress in developing methods to more rapidly evaluate soiling of different materials by PM mixtures. Modern buildings typically have simpler lines, less detailed surfaces, and a greater use of glass, tile, and metal, which are easier to clean than stone. There have also been major changes in the types of materials used for buildings, including a variety of polymers available for use as coatings and sealants. New economic and environmental considerations beyond aesthetic appeal and structural damage are emerging (U.S. EPA, 2019, section 13.4.3). Changes in building materials and design, coupled with new approaches in quantifying the dose-response relationship between PM and materials effects, may reduce the amount of time needed for observations to support the development of material-specific dose-response relationships.

In addition to dose-response functions, damage functions have also been used to quantify material decay as a function of pollutant type and load. Damage can be determined from sample surveys or inspection of actual damage and a damage function can be developed to link the rate of material damage to time of replacement or maintenance. A cost function can then link the time for replacement and maintenance to a monetary cost, and an economic function links cost to the dose of pollution based on the dose-response relationship (U.S. EPA, 2019, section 13.4.3).

Damage functions are difficult to assess because it depends on human perception of the level of soiling deemed to be acceptable and evidence in this area remains limited in the current review. Since the last review, damage functions for a wide range of building materials (i.e., stone, aluminum, zinc, copper, plastic, paint, rubber, stone) have been developed and reviewed (Brimblecombe and Grossi, 2010). One study estimated long-term deterioration of building materials and found that damage to durable building material (such as limestone, iron, copper, and discoloration of stone) is no longer controlled by pollution as was historically documented but rather that natural weathering is a more important influence on these materials in modern times (Brimblecombe and Grossi, 2009). Even as PM-attributable damage to stone and metals has decreased over time, it has been predicted that there will be potentially higher degradation rates for polymeric materials, plastic, paint, and rubber due to increased oxidant concentrations and solar radiation (Brimblecombe and Grossi, 2009).

- **To what extent have important uncertainties identified in the last review been reduced and/or have new uncertainties emerged?**

While there are a number of new studies in the ISA that investigate the effect of PM on newly studied materials and further characterize the effects of PM on previously studied materials, there remains insufficient evidence to relate soiling or damage to specific PM levels or to establish a quantitative relationship between PM in ambient air and materials degradation. Uncertainties that were identified in the last review still largely remain with respect to quantitative relationships between particle size, concentration, chemical concentrations, and frequency of repainting and repair. No new studies are available that link perceptions of reduced aesthetic appeal of buildings and other objects to PM-related materials effects. Moreover, uncertainties about the deposition rates of airborne PM to surfaces and the interaction of co-pollutants still remain.

#### **5.2.2.2 Quantitative Assessment-Based Considerations**

Beyond our consideration of the scientific evidence, discussed above in section 5.2.2.1 above, we also consider the extent to which quantitative analyses of PM air quality and quantitative assessments for climate and materials effects could inform conclusions on the adequacy of the public welfare protection provided by the current secondary PM standards. We have evaluated the potential support for conducting new analyses of PM air quality concentrations and non-visibility welfare effects.

##### **5.2.2.2.1 Climate Effects**

While expanded since the last review, our current understanding of PM-related climate effects is still limited by significant uncertainties. Large spatial and temporal heterogeneities in direct and indirect PM climate forcing can occur for a number of reasons, including the

frequency and distribution of emissions of key PM components contributing to climate forcing, the chemical and microphysical processing that occurs in the atmosphere, and the atmospheric lifetime of PM relative to other pollutants contributing to climate forcing (U.S. EPA, 2019, section 13.3). These issues particularly introduce uncertainty at the local and regional scales in the U.S. that would likely be most relevant to a quantitative assessment of the potential effects of a national PM standard on climate in this review. Limitations and uncertainties in the evidence make it difficult to quantify the impact of PM on climate and in particular how changes in the level of PM mass in ambient air would result in changes to climate in the U.S. Thus, as in the last review, the data remain insufficient to conduct quantitative analyses for PM effects on climate in the current review.

#### **5.2.2.2.2 Materials Effects**

As at the time of the last review, sufficient evidence is not available to conduct a quantitative assessment of PM-related soiling and corrosion effects. While soiling associated with PM can lead to increased cleaning frequency and repainting of surfaces, no quantitative relationships have been established between characteristics of PM or the frequency of cleaning or repainting that would help inform our understanding of the public welfare implications of soiling (U.S. EPA, 2019, section 13.4). Similarly, while some information is available with regard to microbial deterioration of surfaces and the contribution of carbonaceous PM to the formation of black crusts that contribute to soiling, the available evidence does not support quantitative analyses (U.S. EPA, 2019, section 13.4). While some new evidence is available with respect to PM-attributable materials effects, the data are insufficient to conduct quantitative analyses for PM effects on materials in the current review.

### **5.3 CASAC ADVICE**

As part of its review of the draft PA, the CASAC has provided advice on the adequacy of the current PM secondary standards. In its comments on the draft PA, the CASAC concurs with staff's overall preliminary conclusions that it is appropriate to consider retaining the current secondary PM standards without revision (Cox, 2019). The CASAC "finds much of the information...on visibility and materials effects of PM<sub>2.5</sub> to be useful, while recognizing that uncertainties and controversies remain about the best ways to evaluate these effects" (Cox, 2019, p. 13 of consensus responses). Regarding climate, while the CASAC recommends that the EPA consider recent research evaluating the impacts of reducing PM<sub>2.5</sub> and suggests that the EPA include quantitative analyses to more thoroughly address these effects,<sup>26</sup> the committee also

---

<sup>26</sup> While this final PA does consider research evaluating the impacts of PM on climate, we have not conducted analyses to quantify the impacts of changes in U.S. ambient PM concentrations on regional and national climate endpoints in the U.S. that would be of potential relevance for the NAAQS review. This approach to addressing

agrees with the EPA that “the available evidence does not call into question the protection afforded by the current secondary PM standards and concurs that they should be retained” (Cox, 2019, p. 3 of letter).

A number of public comments have been received in this review to date, including comments focused on the draft PA. A limited number of public comment submissions on the draft PA provide comments related to the adequacy of the secondary standards. Of those who provide comments on the secondary standards, the majority of commenters support the preliminary conclusion that it is appropriate to consider retaining the current secondary PM standards, without revision. These commenters generally cite a lack of newly available evidence and information that would inform quantitative assessments and consideration of alternate secondary standards to protect against PM-related effects on visibility, climate, and materials. One commenter (the Independent PM Review Panel), however, supports revision of the secondary PM standards to provide additional protection against PM-related visibility effects, citing inconsistencies between preliminary conclusions in the draft PA to consider retaining the current secondary PM standards and the currently available scientific evidence regarding public visibility preferences and indices for evaluating visibility impairment. This commenter also recognizes the regional heterogeneity in PM<sub>2.5</sub> mass and light extinction and that one single level may not be appropriate in all regions of the country.

## **5.4 CONCLUSIONS ON THE SECONDARY PM STANDARDS**

This section discusses staff conclusions for the Administrator’s consideration in judging the adequacy of the current secondary PM standards. These conclusions are based on consideration of the assessment and integrative synthesis of evidence presented in the ISA, as well as our analyses of recent air quality. Further, the staff conclusions have taken into account advice from the CASAC and public comments on the draft PA and the associated preliminary staff conclusions. Taking into consideration the responses to specific questions discussed above, we revisit the overarching policy question for this chapter:

---

the CASAC’s comments on climate reflects our consideration of the timeline for this review as well as the uncertainties that would be inherent in such analyses and their likely impact on decision making. As discussed above (section 5.2.2.2.1), limitations in the evidence would result in considerable uncertainty in analyses that attempt to quantify the impact of changes in ambient PM in the US on climate in the U.S.

- **Does the currently available scientific evidence and quantitative information support or call into question the adequacy of the protection afforded by the current secondary PM standards?**

As provided in section 109(b)(2) of the CAA, the secondary standard is to “specify a level of air quality the attainment and maintenance of which in the judgment of the Administrator...is requisite to protect public welfare from any known or anticipated adverse effects associated with the presence of such air pollutant in the ambient air.” Effects on welfare include, but are not limited to, “effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility, and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being” (CAA section 302(h)). The secondary standards are not meant to protect against all known or anticipated PM-related effects, but rather those that are judged to be adverse to the public welfare (78 FR 3212, January 15, 2013). Similarly, the extent to which secondary standards are concluded to provide adequate protection from such effects also depends on judgments by the Administrator.

Therefore, we recognize that, as is the case in NAAQS reviews in general, the extent to which the current secondary PM standards are judged to be adequate will depend on a variety of factors and judgments to be made by the Administrator. Such judgments include those concerning the extent or severity of welfare effects that may be considered adverse to the public welfare, and accordingly, what level of protection from such known or anticipated effects may be judged requisite. In general, the public welfare significance of PM-related effects for different air quality conditions and in different locations depend upon the type and severity of the effects, as well as the strength of the underlying information and associated uncertainties. Thus, in the discussion below, our intention is to focus on such aspects of the currently available evidence and quantitative analyses.

With regard to visibility, climate, and materials effects of PM, our response to the question above takes into consideration the discussions that address the specific policy-relevant questions in prior sections of this chapter (see sections 5.2.1 and 5.2.2) and the approach described in section 5.1 that builds on the approach from the last review. With respect to the evidence-based considerations, we note that the currently available evidence, while somewhat expanded since the last review, does not include evidence of effects at lower concentrations or other welfare effects of PM than those identified at the time of the last review. There continue to be significant uncertainties related to quantifying the relationships between PM mass concentrations in ambient air and welfare effects, including visibility impairment, climate effects, and materials effects.

With respect to the visibility effects of PM, the currently available evidence continues to support a causal relationship. With respect to evidence for visibility effects of PM, we note that the currently available evidence, while somewhat expanded since the last review, does not include evidence of effects at lower concentrations than those identified at the time of the last review. Consistent with the evidence available at the time of the last review, significant limitations remain in directly measuring light extinction. However, a number of small refinements have been made to the algorithm commonly used to estimate light extinction (U.S. EPA, 2019, section 13.2.3.3; section 5.2.1.1 above). Light extinction by PM<sub>2.5</sub> is dependent on PM<sub>2.5</sub> composition and relative humidity, which varies regionally, with component contributions to light extinction also changing over time with changes in emissions, as can be seen in analyses of recent air quality. We also note that no new research is available on methods of characterizing visibility or on how visibility is valued by the public, such as visibility preference studies. Thus, while limited new research has further informed our understanding of the influence of atmospheric components of PM<sub>2.5</sub> on light extinction, the available evidence to inform consideration of the public welfare implications of PM-related visibility impairment remains relatively unchanged.

With respect to quantitative-based considerations, analyses using recent air quality and considering updated and alternative methods for estimating visibility impairment provide results generally similar to those given a focus in the decision for the last review. We recognize that conclusions reached regarding visibility in the last review were based primarily on the quantitative analyses that considered the relationship of estimated visibility impairment (light extinction) with design values for the secondary 24-hour PM<sub>2.5</sub> standard. These analyses demonstrated that visibility index values were below 30 dv – the value identified as the target level of protection for visibility-related welfare effects – at all locations that met the daily standard. In our evaluation in this chapter, we have considered the currently available information regarding the equations to estimate light extinction and the inputs to the equations and regarding identification of the target level of protection. With regard to the equations, we have utilized both the most recently published equations as well as alternatives considered in the last review in recognition of the uncertainties inherent in the quantitative relationship between PM and light extinction and the variability in applicability to different locations. Further, we have considered key coefficients in estimating and adjusting concentrations of specific PM<sub>2.5</sub> components, a key example of which is the multiplier used to estimate the concentration of organic matter from the concentration of organic carbon. For consistency with the analysis on which the decision was based in the last review, we have focused on a 3-year average of the 90<sup>th</sup> percentile of daily light extinction (calculated using old and new algorithms) in considering visibility impairment at the analyzed locations.

In reaching a conclusion in the 2012 review with regard to the adequacy of visibility protection provided by the secondary PM standards, the Administrator identified 30 dv as an appropriate target level of protection. We have not identified new information in this review that would challenge this public policy. Thus, in our consideration of the current information and analyses in this document, we have compared the results of the updated analyses to the value of 30 dv, finding only one site that exceeds this target level of protection while meeting the current daily standards, albeit just marginally at 31 dv. In so finding, we additionally note the uncertainties recognized above regarding estimation of OM for use in the IMPROVE equations, and also the variability across sites in characteristics that affect the relationship between PM in ambient air and light extinction, and in characteristics that affect human visibility and preferences in that regard. Based on the findings of this comparison, in light of all of these considerations, we find it reasonable to conclude that the quantitative information available in this review does not call into question the adequacy of visibility-related public welfare protection provided by the current secondary PM standards. As a result, we have not conducted additional analyses to evaluate the level of visibility protection that might be afforded by potential alternative standards.

With respect to the non-visibility welfare effects of PM, the currently available evidence continues to support causal relationships between climate effects and PM and materials effects and PM. The currently available evidence related to climate effects and PM, while expanded since the last review, has not appreciably improved our understanding of the spatial and temporal heterogeneity of PM components that contribute to climate forcing. We note that, as at the time of the last review, the evidence describes differences among individual PM components in their reflective properties and direction of climate forcing. We also note that, while climate research has continued, there are still significant limitations in our ability to quantify contributions of PM, and of individual PM components, to the direct and indirect effects of PM on climate (e.g. changes to the pattern of rainfall, changes to wind patterns, effects on vertical mixing in the atmosphere). While climate models have been improved and refined since the last review, climate models simulating aerosol-climate interactions on regional scales (e.g., ~100 km) tend to have more variability in estimates of the PM-related climate effects than simulations at the global scale, and fewer studies are available that simulate specific regions (e.g., the U.S.) than that provide global-scale simulations. While new research has added to the understanding of climate forcing on a global scale, there remain significant limitations to quantifying potential adverse effects from PM on climate in the U.S. and how they would vary in response to changes in PM concentrations in the U.S. That is, the information currently available with regard to climate does not provide a clear understanding of a quantitative relationship between concentrations of PM mass in ambient air and associated climate-related effects, and consequently, precludes a

quantitative evaluation of the level of protection provided by a PM concentration-based secondary standard from adverse climate-related effects on the public welfare in the U.S. Thus, on the whole, we do not find the currently available information to provide support for different conclusions than were reached in the last review with regard to climate-related effects of PM in ambient air.

In considering the currently available evidence related to materials effects and PM, we note that there is newly available evidence that informs our understanding on the soiling process and types of materials affected, and provides limited information on dose-response relationships and damage functions, although most of the recent evidence comes from studies outside of the U.S. In particular, there is a growing body of research on PM and energy efficiency-related materials, such as solar panels and passive cooling building materials, affecting the optical and thermal properties, thereby impacting the intended energy efficiency of these materials. While new research has added to the understanding of PM-related materials effects, there remains a lack of research related to quantifying materials effects and understanding the public welfare implications of such effects.

In summary, with regard to the two main non-visibility effects – climate effects and materials effects – the available evidence, as in the last review, documents a causal role for PM in ambient air. This evidence, however, as in the last review, also includes substantial uncertainties with regard to quantitative relationships with PM concentrations and concentration patterns that limit our ability to quantitatively assess the public welfare protection provided by the standards from these effects. Thus, as a whole, the current information, which is not appreciably different from that available in the last review, does not call into question the adequacy of protection provided by the current standards for these effects.

Based on all of the above considerations and consistent with CASAC advice, we find that the available evidence does not call into question the protection afforded by the current secondary PM standards against PM-related welfare effects. Thus, our conclusion for the Administrator's consideration is that it is appropriate to consider retaining the current secondary PM standards, without revision. In so concluding, we recognize, as noted above, that the final decision on this review of the secondary PM standards to be made by the Administrator is largely a public welfare judgment, based on his judgment as to the requisite protection of the public welfare from any known or anticipated adverse effects. This final decision will draw upon the available scientific evidence and quantitative analyses on PM-attributable welfare effects, along with consideration of CASAC advice and public comments, and on judgments about the appropriate weight to place on the range of uncertainties inherent in the evidence and analyses.

## 5.5 AREAS FOR FUTURE RESEARCH AND DATA COLLECTION

In this section, we highlight key uncertainties in the available information related to the effects of PM on public welfare. Such key uncertainties and areas for future research, model development, and data gathering are outlined below. We note, however, that a full set of research recommendations is beyond the scope of this discussion. Rather, listed below are key uncertainties, research questions and data gaps that have been thus far highlighted in this review of the secondary PM standards.

- A critical aspect of our consideration of the evidence and quantitative information for visibility impairment is our understanding of human perception of visibility impairment in the preference studies. This is essential to the Administrator's consideration of the public welfare implications of visibility effects and to decisions on the adequacy of protection provided by the secondary PM standards from them. Additional information related to several areas would reduce uncertainty in our interpretation of the available information for purposes of characterizing visibility impairment. These areas include the following:
  - Expanding the number and geographic coverage of preference studies in urban, rural and Class I areas to account for the potential for people to have different preferences based on the conditions that they commonly encounter and potential differences in preferences based on the scene types;
  - Evaluating visibility preferences of the U.S. population today, given that the currently available preference studies were conducted more than 15 years ago, during which time air quality in the U.S. has improved;
  - Accounting for the influence that varying study methods may have on an individual's response as to what level of visibility impairment is acceptable; and
  - Providing insights regarding people's judgments on acceptable visibility based on those factors that can influence an individual's perception of visibility impairment, including the duration of visibility impairment experiences, the time of day during which light extinction is greatest, and the frequency of episodes of visibility impairment, as well as the intensity of the visibility impairment.
- Direct monitoring of PM<sub>2.5</sub> light extinction would help to characterize visibility and the relationships between PM component concentrations and light extinction and to evaluate and refine light extinction calculation algorithms for use in areas near anthropogenic sources, and would provide measurements for future visibility effects assessments.
- Substantial uncertainties still remain with respect to key processes linking PM and climate, because of the small scale of PM-relevant atmospheric processes compared to the resolution of state-of-the-art models, and because of the complex cascade of indirect impacts and feedbacks in the climate system that result from an initial PM-related radiative perturbation. Such uncertainties include those related to our understanding of:
  - The magnitude of PM radiative forcing and the portion of that associated with anthropogenic emissions;

- The contribution of regional differences in PM concentrations, and of individual components, to radiative forcing; and,
  - The process by which PM interacts with clouds and how to represent such interactions in climate models.
- Research on more accurate U.S. and global emission inventories would provide source-specific data on PM and PM component contributions to climate effects, particularly those effects resulting from climate forcing.
- While CASAC highlighted a number of studies as providing quantitative information regarding the impact of reductions in PM<sub>2.5</sub> on direct and indirect climate effects, these studies largely are conducted at a global scale and assume a zeroing out or near-zeroing out of global PM emissions. Research is needed regarding the impacts of incremental changes in PM mass on direct and indirect climate effects on a regional scale, thereby limiting our ability to quantify the impact of these changes at this time.
- Insufficient evidence is available to relate soiling or damage to specific PM concentrations or to establish a quantitative relationship between PM concentrations in ambient air and materials degradation. Additional information would reduce uncertainty in in our interpretation of the available information, including in the following areas:
  - Identifying quantitative relationships between particle size, PM concentration, chemical concentrations, and frequency of repainting and repair;
  - Understanding human perceptions of reduced aesthetic appeal of buildings, and other objects to PM-related materials effects; and
  - Characterizing deposition rates of airborne PM to surfaces and the interaction of co-pollutants.

# APPENDIX A. SUPPLEMENTAL INFORMATION ON PM AIR QUALITY ANALYSES

This appendix provides supplemental information on the data sources and methods used to generate the figures and table presented in Chapter 2 of this PA. Sections A.1 to A.4 describe the data sources and methods used to generate figures and tables in section 2.3.2. Section A.5 describes the data sources and methods used to generate figures and tables in section 2.3.3. Section A.6 describes the data sources and methods used to generate figures and tables in section 2.4.

## A.1 DATA SOURCES AND METHODS FOR GENERATING NATIONAL PM<sub>2.5</sub>, PM<sub>10</sub>, PM<sub>10-2.5</sub>, AND PM<sub>2.5</sub> SPECIATION FIGURES

- PM<sub>2.5</sub> annual average and 98<sup>th</sup> percentile mass concentrations: calculated from regulatory-quality (Federal Reference Method or Federal Equivalent Method) 24-hour average values from monitors with at least 75% completeness for each year. When a single site has multiple monitors, the figure shows the average of the annual averages and 98<sup>th</sup> percentiles from each monitor at the site. We downloaded the monitor-level concentrations for all sites in the United States for all available days (including potential exceptional events) for 2000-2017 from the EPA's Air Quality System (AQS, <https://www.epa.gov/aqs>)
- PM<sub>10</sub> annual average and 98<sup>th</sup> percentile mass concentrations: calculated from both regulatory and non-regulatory methods using 24-hour average values from monitors with at least 75% completeness for each year. When a single site has multiple monitors, the figure shows the average of the annual averages and 98<sup>th</sup> percentiles from each monitor at the site. We downloaded the monitor-level concentrations for all sites in the United States for all available days (including potential exceptional events) for 2000-2017 from the EPA's Air Quality System (AQS, <https://www.epa.gov/aqs>)
- PM<sub>10-2.5</sub> annual average and 98<sup>th</sup> percentile mass concentrations: calculated from both regulatory and non-regulatory methods using 24-hour average values from monitors with at least 75% completeness for each year. When a single site has multiple monitors, the figure shows the average of the annual averages and 98<sup>th</sup> percentiles from each monitor at the site. We downloaded the monitor-level concentrations for all sites in the United States for all available days (including potential exceptional events) for 2000-2017 from the EPA's Air Quality System (AQS, <https://www.epa.gov/aqs>)
- PM<sub>2.5</sub> speciated annual average mass concentrations: calculated from filter-based, 24-hour averages from monitors with at least 75% completeness for each year. We downloaded data from monitors that are part of the Interagency Monitoring of Protected Visual Environments (IMPROVE) network, Chemical Speciation Network (CSN), and the NCore Multipollutant Monitoring Network for 2015-2017.

- The 2000-2017 trends are calculated from the Pearson correlation coefficient for monitors having at least 75% of the available years with 75% completeness within each year. When a single site has multiple monitors, the average of the annual averages and 98<sup>th</sup> percentiles from each monitor at the site is taken prior to calculation of the Pearson correlation coefficient.

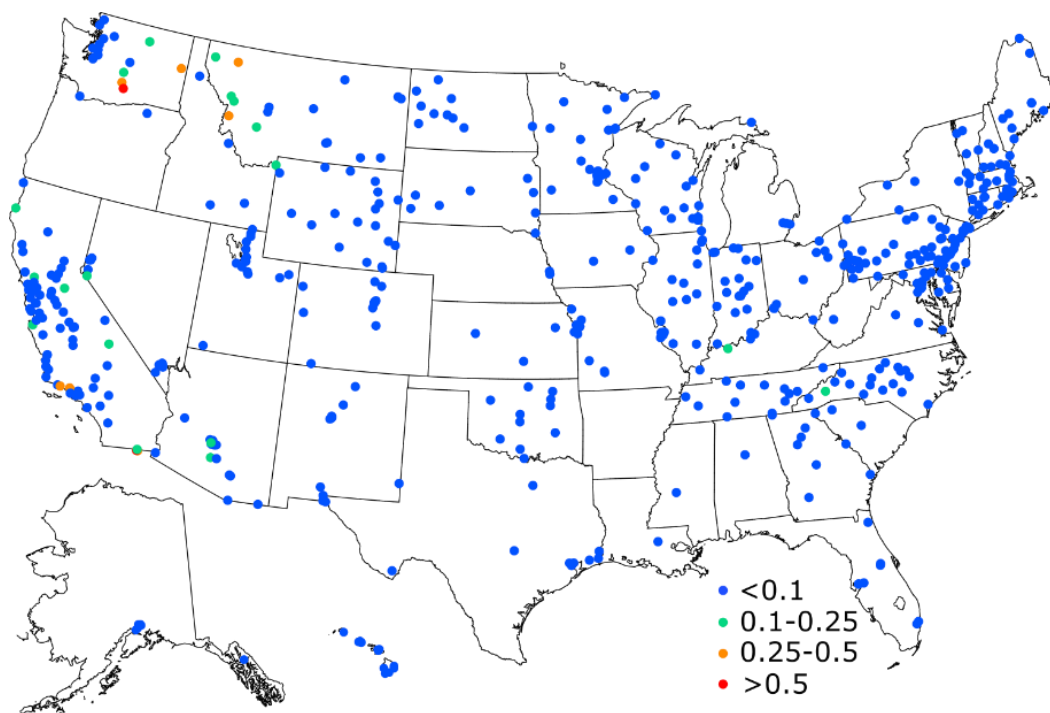

## **A.2 DATA SOURCES AND METHODS FOR GENERATING NEAR-ROAD PM<sub>2.5</sub> DESIGN VALUE TABLE AND INCREMENT FIGURES**

- PM<sub>2.5</sub> design values: calculated using the data handling described by 40 CFR Appendix N to Part 50 - Interpretation of the National Ambient Air Quality Standards for PM<sub>2.5</sub>. We downloaded the design values for all sites in the United States for all available days (including potential exceptional events) for 2015-2017 from the EPA's Air Quality System (AQS, <https://www.epa.gov/aqs>)
- PM<sub>2.5</sub> hourly, daily, and annual average mass concentrations: calculated from regulatory-quality (Federal Reference Method or Federal Equivalent Method) monitors. When a single site has multiple monitors, the figures shows the average from all monitors at the site. We downloaded the monitor-level concentrations for all sites in the United States for all available days (including potential exceptional events) for 2000-2017 from the EPA's Air Quality System (AQS, <https://www.epa.gov/aqs>)
- Near-road sites: designated from the list of near-road sites found at <https://www3.epa.gov/ttnamti1/files/nearroad/Near-road%20Monitoring%20Network%20Site%20List%20-%20May%202017.xlsx>.
- The near-road PM<sub>2.5</sub> increment is calculated by excluding the near-road site within a CBSA, predict the interpolated concentration at the near-road site location using Inverse Distance Weighting (IDW), and subtract the predicted concentration from the actual concentration at the near-road site for each daily or hourly average. Only CBSAs with at least one non-near-road site within 5km of the near-road site are considered. For the Elizabeth, NJ figure, the Elizabeth Lab site was considered a near-road site for the IDW calculation.

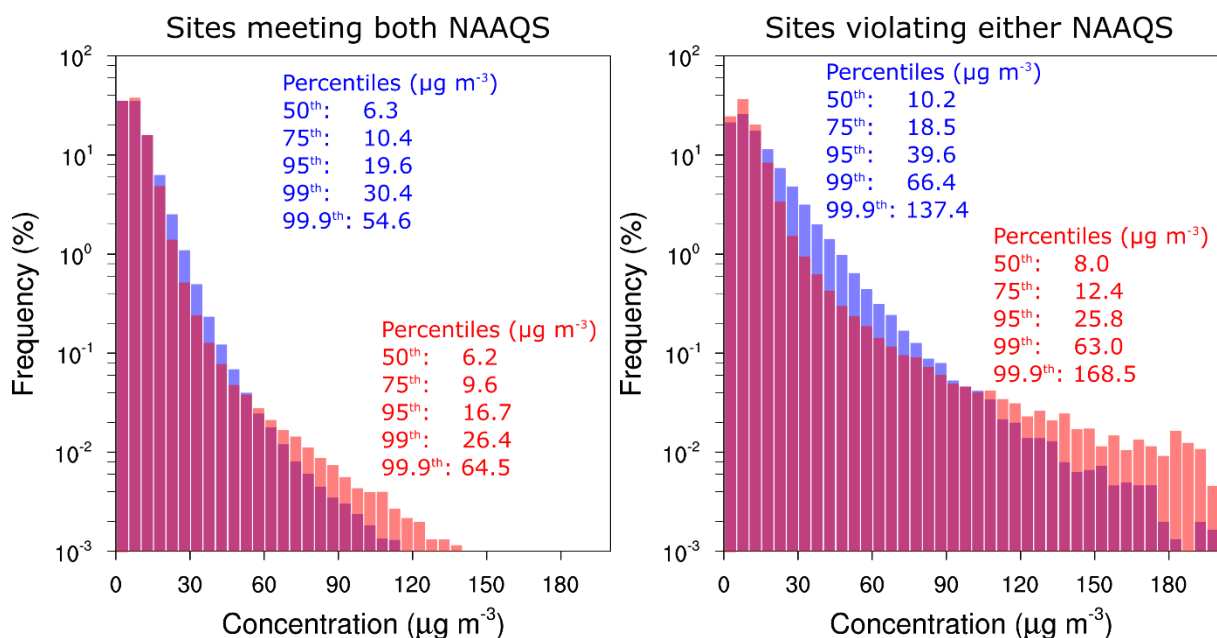

## **A.3 DATA SOURCES FOR SUB-DAILY PM<sub>2.5</sub> CONCENTRATION FIGURE**

- PM<sub>2.5</sub> hourly average mass concentrations: calculated from regulatory-quality Federal Equivalent Method monitors. The 2-hour and 5-hour averages were calculated for periods with each hourly average available. Only sites with a valid annual or 24-hour design value for 2015-2017 are shown in the figure. The percentages of 2-hour average PM<sub>2.5</sub> mass concentrations above 140 µg/m<sup>3</sup> at individual sites are illustrated in Figure A-1. Frequency distributions of 5-hour averages are presented in Figure A-2.

**Figure A-1. Percentages of 2015-2017 2-hour average PM<sub>2.5</sub> mass concentrations above 140 µg/m<sup>3</sup>.**

**Figure A-2. Frequency distribution of 2015-2017 5-hour averages for sites meeting both or violating either PM<sub>2.5</sub> NAAQS for October to March (blue) and April to September (red).**

## A.4 DATA SOURCES FOR ULTRAFINE FRACTION OF PM<sub>2.5</sub> MASS FIGURE

- Annual average particle number and mass concentrations for Bondville, IL: calculated from 24-hour average values for years with 66% data completion in 75% of the months of the year from 2000-2017. We downloaded the mass concentrations from the EPA's Air Quality System (AQS, <https://www.epa.gov/aqs>) and particle number concentrations from NOAA's Earth System Research Laboratory's Global Monitoring Division (<https://www.esrl.noaa.gov/gmd> ).

## A.5 METHODS FOR PREDICTING AMBIENT PM<sub>2.5</sub> BASED ON HYBRID MODELING APPROACHES

### A.5.1 Data Sources for 2011 PM<sub>2.5</sub> Spatial Fields

- The “HU2017” fields were provided by Professor Yang Liu of Emory University in the form of comma-separated-values files (\*.csv) of daily average PM<sub>2.5</sub> on a national grid.
- The “DI2016” fields were provided by Dr. Qian Di of Harvard in the form of MATLAB files (\*.mat) of daily average PM<sub>2.5</sub> on a national grid.
- The “VD2019” fields were provided by Dr. Aaron van Donkelaar in the form of netCDF files (\*.nc) of annual average concentration. These files are also available at: [http://fizz.phys.dal.ca/~atmos/martin/?page\\_id=140](http://fizz.phys.dal.ca/~atmos/martin/?page_id=140).
- The “downscaler” files were developed in terms of daily average Downscaler predictions on a national grid following methods described in the risk assessment appendix.

### A.5.2 Data Averaging and Coefficient of Variation

- PM<sub>2.5</sub> concentration fields were loaded into R version 3.4.4, and daily fields were averaged to the annual period. Concentrations for each method at prediction points were then averaged to the corresponding CMAQ grid cells to enable consistent comparisons for Figure 2-24, 2-26, and Table 2-3.
- The coefficient of variation (CoV) was calculated for each grid cell using the following formula

$$CoV(\%) = \frac{100}{\bar{P}} \sqrt{\frac{\sum_{i=1}^N (P_i - \bar{P})^2}{N}}$$

where P is the prediction for each of the four methods (i.e., N=4).

## A.6 ANALYSES OF BACKGROUND PM

- Data sources for Figure 2-30: Smoke and fire detections observed by MODIS in August 2017
  - Image was produced using the NASA Worldview platform (<https://worldview.earthdata.nasa.gov/>). Layers selected were 1) Corrected

Reflectance and 2) Fires and Thermal Anomalies, both from Aqua/MODIS. Day selected was August 4, 2017.

- Data sources for Figure 2-31: Fine PM mass time series during 2017 from North Cascades IMPROVE site
  - Image was archived from the IMPROVE website ([http://views.cira.colostate.edu/fed/SiteBrowser/Default.aspx?appkey=SBCF\\_PmHazeComp](http://views.cira.colostate.edu/fed/SiteBrowser/Default.aspx?appkey=SBCF_PmHazeComp); hosted by CIRA/CSU and sponsored by NPS and USFS) for the North Cascades (NOCA1) site in 2017.
- Data sources for Figure 2-32: Speciated annual average fine PM mass from IMPROVE at select remote monitors in 2004 and 2016
  - Speciated IMPROVE data from 2004 and 2016 ([http://views.cira.colostate.edu/fed/SiteBrowser/Default.aspx?appkey=SBCF\\_PmHazeComp](http://views.cira.colostate.edu/fed/SiteBrowser/Default.aspx?appkey=SBCF_PmHazeComp)) were averaged annually for each monitor. Corresponding monitor locations are shown in Figure 2-32.

## **APPENDIX B. DATA INCLUSION CRITERIA AND SENSITIVITY ANALYSES**

## TABLE OF CONTENTS

This appendix presents supplemental information on the methods used to conduct the analyses discussed in section 3.2.3.2 of this PA. It also presents information on additional sensitivity analyses. Section B.1 provides supplemental information on the forest plots presented in Figures 3-3 to 3-6. Sections B.2 and B.3 provide supplemental information on the study-reported PM<sub>2.5</sub> concentrations presented in Figure 3-7 and Figure 3-8. Sections B.4 to B.6, and sections B.8 to B.10, present supplemental information and sensitivity analyses related to the analyses of study area pseudo-design values in section 3.2.3.2.2. Section B.7 presents comparisons between annual and daily design values in CBSAs.

## **B.1 FOREST PLOTS**

Forest Plots exhibiting effect estimates and 95% confidence intervals from epidemiologic studies that have the potential to be most informative in reaching conclusions on the adequacy of the current primary PM<sub>2.5</sub> standards are shown in Figure 3-3 to Figure 3-6. Epidemiologic studies included in these figures support “causal” or “likely to be causal” relationships with PM exposures in the ISA U.S. EPA, 2019 and include mortality (all-cause mortality, CVD mortality, respiratory mortality, lung cancer mortality), and morbidity (asthma incidence, lung cancer incidence, lung function and lung development, CVD and respiratory emergency room visit or hospital admission) health endpoints. Further, studies included in Figure 3-3 to Figure 3-6 were restricted to multi-city studies in the United States or Canada. Multi-city studies within a single State were not included, with the exception of respiratory morbidity endpoints, where multi-city studies were limited. For some of the major cohort studies included in the previous ISA, like the American Cancer Society (ACS) cohort, we included new studies that reanalyze epidemiologic associations for multiple mortality endpoints (e.g. lung cancer mortality and IHD mortality) and an extension of follow-up periods (e.g., Pope et al. (2015b), Turner et al. (2016), Jerrett et al. (2016), and Thurston et al. (2016b)), as well as a reanalysis (Krewski et al. (2009) of the original ACS dataset, including an extended follow-up period, that was evaluated in the previous ISA (EPA, 2009). In total, 67 studies were included in Figure 3-3 to Figure 3-6.

## **B.2 MONITORED PM<sub>2.5</sub> CONCENTRATIONS IN KEY EPIDEMIOLOGIC STUDIES**

Of the 67 key studies identified in Figure 3-3 to Figure 3-6, Figure 3-7 includes key epidemiologic studies that report an overall study mean or median concentration of PM<sub>2.5</sub> (as opposed to a study mean/median range across study area locations) and based on ambient PM<sub>2.5</sub>

monitored data. The plot includes studies that report significant effect estimates (22 studies) and studies that only report non-significant effect estimates (5 studies). Further, to be included, only key studies for which the years of air quality data used to estimate exposures overlap entirely with the years during which health events are reported were included. The PM<sub>2.5</sub> concentrations reported by studies that estimate exposures from air quality corresponding to only part of the study period, often including only the later years of the health data (e.g., Miller et al., 2007; Hart et al., 2011; Thurston et al., 2013; Weichenthal et al., 2014; Weichenthal et al., 2016a; Pope et al., 2015a; Villeneuve et al., 2015; Turner et al., 2016), are not likely to reflect the full ranges of ambient PM<sub>2.5</sub> concentrations that contributed to reported associations.<sup>1</sup>

Some of the included studies also provide city-specific study mean concentrations and city-specific health events. Hence, PM<sub>2.5</sub> exposure estimates corresponding to the 10<sup>th</sup> and 25<sup>th</sup> percentiles of those events were determined in the following manner. City-specific cases and PM<sub>2.5</sub> concentrations were input in ascending order by PM<sub>2.5</sub> concentration. The city-specific percent of cases was calculated as a proportion of the total study cases and the cumulative percent of cases was determined. The PM<sub>2.5</sub> concentration associated with the cumulative percent closest to the 10<sup>th</sup> and 25<sup>th</sup> percentiles were input in Figure 3-7 and the cumulative percent values closest to the associated 10<sup>th</sup> and 25<sup>th</sup> percentile inputs are shown in Table B-1<sup>2</sup>. Data for Bell et al. (2008) and Zanobetti and Schwartz (2009) were previously provided by the study authors, as described in Rajan (2011).

**Table B-1. PM<sub>2.5</sub> concentrations corresponding to the 25<sup>th</sup> and 10<sup>th</sup> percentiles of estimated health events.**

Citation	10 <sup>th</sup> Percentile PM <sub>2.5</sub> (µg/m <sup>3</sup> ) (Cumulative percent value closest)	25 <sup>th</sup> Percentile PM <sub>2.5</sub> (µg/m <sup>3</sup> ) (Cumulative percent value closest)
Bell et al. (2008)	9.8	11.5
Franklin et al. (2007)	10.4 (11.1%)	12.9 (25.3%)
Stieb et al. (2009)	6.7 (16.5%)	6.8 (20.5%)
Szyszkowicz (2009)	6.4 (4.1%)	6.5 (18.6%)
Zanobetti and Schwartz (2009)	10.3	12.5

<sup>1</sup> This is an issue only for some studies of long-term PM<sub>2.5</sub> exposures. While this approach can be reasonable in the context of an epidemiologic study evaluating health effect associations with long-term PM<sub>2.5</sub> exposures, under the assumption that spatial patterns in PM<sub>2.5</sub> concentrations are not appreciably different during time periods for which air quality information is not available (e.g., Chen et al., 2016), our interest is in understanding the distribution of ambient PM<sub>2.5</sub> concentrations that could have contributed to reported health outcomes.

<sup>2</sup> That is, 25% of the total health events occurred in study locations with mean PM<sub>2.5</sub> concentrations (i.e., averaged over the study period) below the 25<sup>th</sup> percentiles identified in Figure 3-7 and 10% of the total health events occurred in study locations with mean PM<sub>2.5</sub> concentrations below the 10<sup>th</sup> percentiles identified.

### B.3 HYBRID MODEL PREDICTED PM<sub>2.5</sub> CONCENTRATIONS IN KEY EPIDEMIOLOGIC STUDIES

Figure 3-8 focuses on multicity studies that are part of the evidence supporting “causal” or “likely to be causal” determinations in the ISA and that use air quality data to estimate PM<sub>2.5</sub> exposures for the entire range of years during which health events occurred. In addition, as detailed in section 3.2.3.2.1, we also consider the approach used to validate model predictions, and the studies included in Figure 3-8 are those for which relatively robust model validation analyses are reported to have been conducted for the full range of years during which PM<sub>2.5</sub> exposures are estimated in the health study.<sup>3</sup> All studies that met the criteria for inclusion were conducted in the U.S.

Figure 3-8 presents overall means of hybrid model-predicted PM<sub>2.5</sub> concentrations for key studies, and the concentrations corresponding to the 25<sup>th</sup> and 10<sup>th</sup> percentiles of estimated exposures or health events, when available. For Di et al. (2017b), we present 25<sup>th</sup> and 10<sup>th</sup> percentiles of annual PM<sub>2.5</sub> concentrations by zip code corresponding to long-term exposure estimates, while for Di et al. (2017a), we present daily air pollution concentrations (short-term exposure estimates) corresponding to the 25<sup>th</sup> and 10<sup>th</sup> percentiles of deaths at the zip-code level. These values, along with other percentiles, are illustrated in Figure B-1 and Figure B-2 (Jenkins, 2019a, Jenkins, 2019b). The study authors for Di et al. (2017b) additionally provided information on population weighted percentile values corresponding to long-term PM<sub>2.5</sub> exposure (Chan, 2019). These are presented in Table B-2. For other studies included in Figure 3-8 [Kloog et al. (2012), Kloog et al. (2014), Shi et al. (2016), Wang et al. (2017)], 25<sup>th</sup> percentiles of exposure estimates were derived from study manuscripts of air quality descriptive statistics and can be found in Table B-3.

---

<sup>3</sup> For example, due to lack of spatial field availability before 1998, Crouse et al. (2015) use median annual PM<sub>2.5</sub> concentrations for the 1998-2006 time period (van Donkelaar et al., 2010; van Donkelaar et al., 2015a; van Donkelaar et al., 2013) to predict exposures during the 1984-2006 period. Similarly, for Pinault et al. (2016), model validation is for 2004 to 2008 (van Donkelaar et al., 2015b) while exposures are estimated for 1998 to 2012. Paciorek et al. (2009), which presents the model validation results for Puett et al. (2009) and Puett et al. (2011), notes that PM<sub>2.5</sub> monitoring was sparse prior to 1999, with many of the available PM<sub>2.5</sub> monitors in rural and protected areas. Therefore, Paciorek et al. (2009) conclude that coverage in the validation set for most of the study period (1988-1998) is poor and that their model “strongly” underestimates uncertainty Paciorek et al. (2009), p. 392 in published manuscript). Hystad et al. (2013) used exposure fields developed by calibrating satellite-based PM<sub>2.5</sub> surfaces from a recent period (van Donkelaar et al., 2010) to estimate exposure for the 1975 to 1994 (Hystad et al., 2012). Hystad et al. (2012) noted that a random effect model was used to estimate PM<sub>2.5</sub> based on TSP measurements and metropolitan indicator variables because only small number of PM<sub>2.5</sub> measurements were available, and no measurements were made prior to 1984. Thus, these studies are not included in Figure 3-8.

# Percentiles of PM<sub>2.5</sub> By Zip Code

Thresholds defining percentiles of PM<sub>2.5</sub> exposure for each zip code.

Percentile of PM <sub>2.5</sub> , Based on ZIP code	PM <sub>2.5</sub> Value

## B.4 DESIGN VALUE BOX PLOT INCLUSION CRITERIA

Studies selected from Figure 3-3 to Figure 3-6 for inclusion in Figure 3-9 and Figure B-9 (box plots of pseudo-design value distributions) are those studies that define the study area/s (city or county) and study-specific populations or study area health events. Studies that provide county/city-specific health counts across the study period include: Lepeule et al. (2012); Kioumourtzoglou et al. (2016); Franklin et al. (2008); Zanobetti et al. (2014); Yap et al. (2013); Ostro et al. (2016); and Weichenthal et al. (2016b). In U.S. studies for which health counts were not provided, county-specific population data derived from the 2015 American Community Survey data<sup>4</sup> was used. For Canadian studies, city-specific population from 2016 Statistics Canada<sup>5</sup> was used.

In constructing the plots in Figure 3-9 and Figure B-9, several assumptions were made. In studies that report mortality, hospital admissions data or emergency department visits, it was assumed that the number of cases is directly proportional to the population of the area. To test this assumption, census population data and case event data is used in a sensitivity analysis and discussed in Section B.6. It was assumed that the population of a county did not change substantially over time relative to other counties, and that the rank order is consistent over time since only U.S. 2015 Census data and 2016 data from Statistics Canada was used. In studies that state the study area is the entire U.S. (*i.e.* in Medicare studies), it was assumed that cases came from each county of the U.S. (*i.e.*, proportional to the county population 65 years or older for Medicare studies) and therefore, air quality was used from all U.S. counties with data.

<sup>4</sup>Available from: <https://data.census.gov/cedsci/>

<sup>5</sup> Available from: <https://www12.statcan.gc.ca/census-recensement/2016/dp-pd/prof/index.cfm?Lang=E&TABID=1>

Studies that had health data that started before 1999 in the U.S. and before 2000 in Canada were excluded since U.S. and Canadian PM<sub>2.5</sub> monitoring became more widespread starting around these times. 29 studies met these criteria and are found in Figure 3-9 and Figure B-9. Details on study-area assignment (Section B.4.1), population/health events assignment (Section B.4.2), and air quality linkages (Section B.4.3) for studies included in the pseudo-design value (DV) box plots are outlined below.

#### **B.4.1 Study area assignment**

The first step in developing Figure 3-9 and Figure B-9 was to identify the study area. The U.S. based analysis is at the county-level and each U.S. county within the study area was identified for each specific study. For the studies that provided city names, the U.S. cities were used to identify all counties from the metropolitan area of that city, unless the entire city is contained within a single county or unless otherwise noted. In cases of studies where the study authors state that data was used for the entire U.S., all U.S. counties were included in the study area assignment. For example, all counties were included in studies using Medicare or National Center for Health Statistics (NCHS) data, unless the study identified a subset of cities or counties included. For some studies, there are uncertainties related to how we chose counties to represent study areas. Many studies identify the counties or cities used for the study; however, some only said that they used HA or ED visit data from a specific state or region and didn't specify any counties or cities. In those instances, we operated under the assumption that every county that fell within the state or region identified contributed to the study population.<sup>6</sup>

For studies based in Canada, city was used as the geographic unit for the study area, since Canadian air quality data is available at the city-level. In cases where a study notes that the study is a national study, all cities for which air quality was available were included to define the study area.

Studies were excluded from Figure 3-9 and Figure B-9 if the counties included are unclear or not identified. Studies were also excluded in situations where the study population selection criteria was not random and not likely to be proportional to the underlying population, or the population selection criteria was not clearly specified (e.g., such as in cohort studies like the American Cancer Society cohort (ACS), Nurses' Health Study cohort (NHS), and the Health Professionals Follow-up Study (HPFS)).

#### **B.4.2 Study population assignment**

Based on the study areas identified in step 1, area-specific health events or populations were then assigned to U.S. counties and Canadian cities. If the study reported health events for

---

<sup>6</sup> As discussed below (section B.4.3), not all counties have PM<sub>2.5</sub> monitor.

U.S. counties or Canadian cities, we assigned those events to the specific counties or cities identified. In the absence of reported health events at these geographic levels for studies where hospital admissions or emergency department visits data, Medicare data, NCHS data, or other national survey data was used, we assumed that study participants were randomly selected and that the number of health events reported in the study was directly proportional to the population of the area. For these studies, area-specific populations were assigned using U.S. 2015 American Community Survey population data or 2016 Canadian population data (Statistics Canada).<sup>7</sup> For the remaining studies (i.e., for which the number of study participants or health events in each location was not provided and for which the study population selection process appeared to not be random or proportional to underlying populations), area-specific populations were not assigned, and the studies were excluded from analysis.

In U.S. studies that evaluate cities, and for which some cities are associated with more than one county, 2016 “City-to-County finder” data from Stats America<sup>8</sup> was used to find the proportional distribution of city population within each county, and the same proportional distribution strategy was used to divide the reported health events between counties. An example of the proportional distribution of city populations within counties is illustrated in Table B-4, using a subset of cities reported in Zanobetti et al. (2014). Note, for cities not listed in Table B-4, the city population was associated with one county and as a result, the health events for the specific city were assigned to the corresponding county.

**Table B-4. Percent of population by county associated with each city reported in the study area.**

City	Counties (% of population)
Atlanta, GA	Dekalb (6.7%), Fulton (93.3%)
Austin, TX	Travis (95.5%), Williamson (4.5%)
Columbus, OH	Franklin (97.9%), Fairfield (1.2%)
Dallas, TX	Dallas (93.9%), Collin (3.9%), Denton (2.2%)
Fort Worth, TX	Tarrant (99%), Denton (1%)
Holland, MI	Ottawa (78.8%), Allegan (21.2%)
Houston, TX	Harris (98%), Fort Bend (2%)
Lansing, MI	Ingham (96%), Eaton (4%)
Middletown, OH	Butler (94.5%), Warren (5.5%)

<sup>7</sup> While this approach contributes uncertainty to our analyses of pseudo-design values, we do not expect the rank order of county population to substantially differ over the time periods of the studies and, therefore, we do not expect this uncertainty to systematically bias our results.

<sup>8</sup> Available from: <http://www.statsamerica.org/Default.aspx>

New York, NY	Kings (30.6%), Queens (27.3%), New York (19.4%), Bronx (16.9%), Richmond (5.7%)
Oklahoma City, OK	Oklahoma (81.3%), Cleveland (11%), Canadian (7.7%)
Tulsa, OK	Tulsa (98.4%), Osage (1.6%)
Charleston, SC	Charleston (93.3%), Berkeley (6.7%)

#### B.4.3 Air Quality data assignment by study area, by study period

The third step in developing Figure 3-9 and Figure B-9 was to assign air quality data by study area, by study period. Ambient air quality data for PM<sub>2.5</sub> in the United States and Canada became more widely available across a broad proportion of the United States and Canada in the late 1990s. To ensure a large proportion of air quality data points and subsequent 3-year design values were available, the studies selected were those that examine air quality data starting in 1999 for U.S. studies and 2000 for Canadian studies. Construction of pseudo-design value box plots (Figure 3-9 and Figure B-9) is described below. The air quality metric is termed a “pseudo-design value”, since both FRM/FEM monitors, as well as high quality non-FRM/FEM data, are used to expand the number of areas with air quality data.<sup>9</sup> Air quality data in the U.S. was obtained from the EPA Air Quality System (AQS)<sup>10</sup>. For regulatory monitors, design values were calculated using the data handling described by 40 CFR Appendix N to Part 50 - Interpretation of the National Ambient Air Quality Standards for PM<sub>2.5</sub>. For non-regulatory data, only monitors with 75% completeness for each of the 12 quarters in a 3-year design value period were included. For Canadian air quality data, only sites with 75% completeness for each year of the 3-year design value period were included.<sup>11</sup> These criteria are slightly different than that of actual design values, which have strict rounding conventions and substitution tests for sites with less than 75% completeness for each quarter. For each given study and each previously identified study area, each valid pseudo-DV was identified over each study period. For each county, or city, the maximum PM<sub>2.5</sub> pseudo-design value for each 3-year period of the study was identified. Next, by county/city, the study-period average of the maximum pseudo-design value was calculated (“average maximum pseudo-design value” or “average max pseudo-DV”). For each study, locations were ordered by increasing average max pseudo-DVs and the corresponding population or number of health events was used to calculate the cumulative percent of population

<sup>9</sup> As noted in section B.5, sensitivity analyses using only regulatory FRM/FEM monitors gave similar results.

<sup>10</sup> Available from: <https://www.epa.gov/aqs>

<sup>11</sup> Available from: <http://maps-cartes.ec.gc.ca/rnsps-naps/data.aspx?lang=en>

at or below each corresponding average max pseudo-DV. Next, the average max pseudo-DV associated with the cumulative population closest to the 5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup> and 95<sup>th</sup> percentiles were identified. The actual cumulative percents that are closest to the 5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup>, and 95<sup>th</sup> percentiles, for all long- and short-term exposure studies and for annual and 24-hr PM<sub>2.5</sub> concentrations, are illustrated in Figure B-3 and Figure B-4. The average max pseudo-DVs associated with these percentiles in these studies are then presented in Table B-5 and Table B-6. Counties that had no air quality monitors or no valid design values did not contribute to the percentile calculation.

<sup>12</sup> As a sensitivity analysis, we also calculated study period averages of maximum design values using only regulatory FRM/FEM monitors for Di et al. (2017a) and Di et al. (2017b) and Shi et al. (2016). Results were similar to those based on the pseudo-design values using both regulatory and non-regulatory monitors. Using only regulatory monitors for the studies by Di et al. (2017a) and Di et al. (2017b), 5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup> and 95<sup>th</sup> percentiles of annual design values were 7.4, 9.7, 11.7, 13.9 and 17.6 µg/m<sup>3</sup>, respectively. For these studies, 5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup> and 95<sup>th</sup> percentiles of 24-hour design values were 19, 26, 30, 36 and 49 µg/m<sup>3</sup>, respectively. For Shi et al., 2016, 5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup> and 95<sup>th</sup> percentiles of annual design values were 7.7, 9.1, 10.4, 11.4 and 13.0 µg/m<sup>3</sup>, respectively while 5<sup>th</sup>, 25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup> and 95<sup>th</sup> percentiles of 24-hour design values were 21, 26, 29, 31 and 35 µg/m<sup>3</sup>, respectively.

For each study in Figure 3-9 and Figure B-9, an assessment of the percent of 3-year average pseudo-DVs available for each study area and study period is presented in Figure B-5. For example, in a study with a study area of 5 counties that was completed for study a period from 2000-2004, 3 possible 3-year average pseudo-DVs exist per county (*i.e.* 2000-2002, 2001-2003, and 2002-2004), with a total of 15 possible pseudo-DVs. However, if one county only has one valid 3-year average pseudo-DV, then the study would have 13 out of a possible 15 pseudo-DVs. Figure B-5 displays a percent of 3-year average pseudo-DV data points available in each study.

**Figure B-5. Studies used in box-and-whisker plots (Figure 3-9 and Figure B-9) and the percent of pseudo-DVs available by study.**

There are important uncertainties to consider when assigning air quality to a study area. Pseudo-design values are based on individual monitors in each county included in study areas. Counties may or may not reflect actual non-attainment areas, which can include multiple counties or parts of counties. For studies conducted in Canada, this potential mismatch is of greater concern. Pseudo-design values are not actual design values. Our analyses considered all available monitoring data, even from monitors not meeting strict completeness requirements for determining non-attainment. While we conclude this is a reasonable approach, as it allows the consideration of ambient PM<sub>2.5</sub> concentrations in a greater proportion of study areas than if the analysis were restricted only to valid design values, it remains an uncertainty in our analyses. Additional uncertainties are discussed above in section 3.2.3.2.2.

## **B.5 PERCENT OF STUDY AREA POPULATION CAPTURED IN DESIGN VALUE PLOTS**

Figure 3-9 and Figure B-9 include annual (Figure 3-9) and 24-hour (Figure B-9) pseudo-design values corresponding to 5,25,50,75, and 95<sup>th</sup> percentiles of study populations or health events for U.S. and Canadian studies of long-term or short-term exposures, and for studies of mortality or morbidity outcomes. Further analyses were completed to determine the proportion of the study area populations captured in these analyses. Within each study, the cumulative population of counties with a valid 3-year average pseudo-DV was determined as a proportion of the total population in counties included in the study. For example, if valid air quality data was available in each county of the study area, then 100% of the study area population would be captured within the design value box plots. For most studies included in Figure 3-9 and Figure B-9, valid pseudo-DVs are available for counties accounting for at least about 70% of the total study area population (Table B-7 and Table B-8).

When design values are calculated using only the regulatory monitors, as discussed in section B.4.3 above, the total study area population captured in the calculation declines. For example, for Di et al. (2017b) and Di et al. (2017a), when calculation of design values was completed using air quality data only from regulatory monitors, the analyses captured 67.35% of population for annual design values (compared to 70.38% of population for annual pseudo-design values when data from all monitors was used). Similarly, analyses captured 67.43% of population for 24-hour design values from regulatory monitors alone, compared to 70.47% of population for pseudo-design values when data from all monitors was used. For Shi et al. (2016), calculation of annual and 24-hour design values from regulatory monitors captured 71.37% of population, compared to 77.22% of population when data from all the monitors was used.

**Table B-7. Percent population included in annual pseudo-DV boxplots (Figure 3-9).**

## **B.6 SENSITIVITY ANALYSIS: BOX PLOTS USING COUNTS OF HEALTH EVENTS VERSUS STUDY AREA POPULATION**

As discussed in Section 3.2.3.2.2, Figure 3-9 and Figure B-9 present box-and-whisker plots reflecting the PM<sub>2.5</sub> 3-year average maximum pseudo-design values that correspond to various percentiles of the study area population or study area health events. When area-specific health events are available, Figure 3-9 and Figure B-9 present percentiles of air quality and study area health events. There is uncertainty regarding the extent to which the populations in counties included in key studies reflect the true distribution of cases in those studies. Many studies used registry data, or similar data sources that may be expected to capture the majority of cases within a study location; however, these studies often didn't report the exact number of cases per area. When the number of cases were not available, we instead used the underlying county-level population obtained using 2015 U.S. census data. While this approach contributes uncertainty to our analyses of pseudo-design values, for the limited number of studies with information on the number of cases per county, the distributions of pseudo-design values relative to the number of cases were similar to the distributions relative to the county population (particularly for annual pseudo-design values). Figure B-6 provides a comparison of studies where health event data are available, to assess the distribution of pseudo-design values when study area population is used versus study area health events.

**Figure B-6. PM<sub>2.5</sub> pseudo-design values corresponding to various percentiles of study area populations and health events for studies of 24-hour PM<sub>2.5</sub> exposures and long-term studies (top panel) and annual PM<sub>2.5</sub> exposures and long-term studies (bottom panel).**

## B.7 COMPARISONS BETWEEN ANNUAL AND DAILY DESIGN VALUES

As discussed above in section 3.2.3.2, for an area to meet the NAAQS, all valid design values in that area, including the highest annual and 24-hour values, must be at or below the levels of the standards. Because monitors are often required in locations with high PM<sub>2.5</sub> concentrations (section 2.2.3), areas meeting an annual PM<sub>2.5</sub> standard with a particular level would be expected to have long-term average PM<sub>2.5</sub> concentrations (i.e., averaged across space and over time in the area) somewhat below that standard level. Figure B-7 and Table B-9

indicate that, based on recent air quality in U.S. CBSAs, maximum annual PM<sub>2.5</sub> design values are often 10% to 20% higher than annual average concentrations (i.e., averaged across multiple monitors in the same CBSA). The difference between the maximum annual design value and average concentration in an area can be smaller or larger than this range, likely depending on factors such as the number of monitors, monitor siting characteristics, and the distribution of ambient PM<sub>2.5</sub> concentrations. Given that higher PM<sub>2.5</sub> concentrations have been reported at some near-road monitoring sites, relative to the surrounding area (section 2.3.2.2.2), recent requirements for PM<sub>2.5</sub> monitoring at near-road locations in large urban areas (section 2.2.3.3) may increase the ratios of maximum annual design values to averaged concentrations in some areas. Such ratios may also depend on how the average concentrations are calculated (i.e., averaged across monitors versus across modeled grid cells). Compared to annual design values, Figure B-8 indicates a more variable relationship between maximum 24-hour PM<sub>2.5</sub> design values and annual average concentrations.

**Figure B-7. Comparison of CBSA average annual design values and CBSA maximum annual design values for 2015-2017.** (Note: Includes all CBSAs with at least 3 valid annual DVs.)

**Table B-9. National Averages of ratios of maximum annual design values to averaged concentrations.**

Year of monitoring data	Number of monitors per CBSA	Number of CBSAs	Ratio of max Annual DV to CBSA average	Ratio of max 24-hr DV to CBSA average
2009-2011	3 or more	67	1.12	1.13
	4 or more	33	1.14	1.16
	5 or more	18	1.17	1.19
2012-2014	3 or more	60	1.15	1.15
	4 or more	38	1.17	1.18
	5 or more	23	1.19	1.21
2015-2017	3 or more	65	1.16	1.19
	4 or more	38	1.19	1.21
	5 or more	30	1.20	1.24

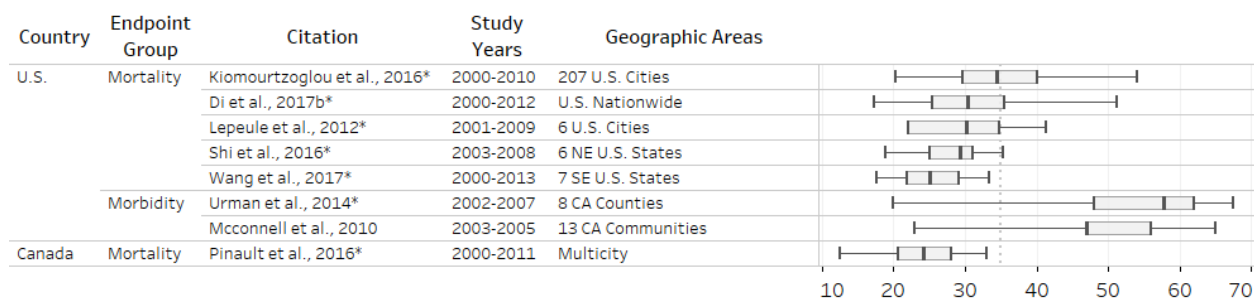

**Figure B-8. Comparison of CBSA average annual design values and CBSA maximum daily design values for 2015-2017.** (Note: Dashed lines indicate the level of the current 24-hour PM<sub>2.5</sub> standard (35  $\mu\text{g m}^{-3}$ ) and the current annual PM standard (12  $\mu\text{g m}^{-3}$ ). Includes all CBSAs with at least 3 valid daily and 3 valid annual DVs.)<sup>13</sup>.

<sup>13</sup> The CBSA maximum 2015-2017 daily design value (y-axis) was cut off at 60  $\mu\text{g m}^{-3}$ , to improve the visualization of data, but this removed the Fairbanks CBSA from the plot, which had a daily design value of 85  $\mu\text{g m}^{-3}$  and an annual design value of 15.7  $\mu\text{g m}^{-3}$ .

## **B.8 24-HOUR PSEUDO-DESIGN VALUES AND DISTRIBUTIONS ACROSS STUDY AREAS**

As described in section 3.2.3.2.2 of the PA, and section B.4 of this appendix, for locations evaluated in key epidemiologic studies we identify annual and 24-hour PM<sub>2.5</sub> pseudo-design values and the number of people (or health events). Figure 3-9 in the PA presents box-and-whisker plots summarizing those data for annual pseudo-design values. Figure B-9 (below) presents box-and-whisker plots summarizing those data for 24-hour pseudo-design values.

## Long-term exposure studies

## Short-term exposure studies

**Figure B-9. PM<sub>2.5</sub> 24-hour pseudo-design values corresponding to various percentiles<sup>[1]</sup> of study area populations or health events for studies of long-term and short-term PM<sub>2.5</sub> exposures.<sup>[2]</sup>**

<sup>[1]</sup> Whiskers reflect PM<sub>2.5</sub> pseudo-design values corresponding to 5<sup>th</sup> and 95<sup>th</sup> percentiles of study area populations (or health events), boxes correspond to the 25<sup>th</sup> and 75<sup>th</sup> percentiles, and the vertical lines inside the boxes correspond to 50<sup>th</sup> percentiles. Asterisks next to study citations denote statistically significant effect estimates.

<sup>[2]</sup> For most of the studies included in Figure B-9, pseudo-design values are available for >70% of study area populations (or health events). Exceptions are Kloog et al. (2012), Lee et al. (2015b), Pinault et al. (2016), Wang et al. (2017), and Bravo et al. (2017), with pseudo-design values available for 65%, 48%, 51%, 68%, and 64% of study area populations, respectively.

## **B.9 PSEUDO-DESIGN VALUE DISTRIBUTION BY AVERAGE COUNTY PSEUDO-DESIGN VALUES PER 1 $\mu\text{G}/\text{M}^3$**

Figure 3-9 and Figure B-9 exhibit distributions of pseudo-DVs corresponding to study areas within each study and based on averaging pseudo-DVs. That is, for each study location, maximum 3-year pseudo-design values are averaged over study periods. Depending on the years of air quality evaluated by the study, for some locations those averages could reflect air quality that violated the current standards during part of the study period and met the current standards during part of the study period. We have examined this issue in greater detail for the studies by Di et al. (2017b) and Shi et al. (2016).

Figure B-10 and 0 present the relationship between annual pseudo-DVs averaged over the study period and the individual 3-year pseudo-DVs that contribute to those study-period averages for Di et al. (2017b). Of the 6,315 3-year pseudo-DVs available for this study, 3,915 (62%) are less than or equal to  $12.04 \mu\text{g}/\text{m}^3$  (i.e., lower than the current annual standard). Of the counties that have study-period average pseudo-DV's  $\leq 12.04 \mu\text{g}/\text{m}^3$ , 89.3% of individual 3-year pseudo-DVs are  $\leq 12.04 \mu\text{g}/\text{m}^3$  (i.e., 3,410 of 3,820 3-year pseudo-DVs).

**Figure B-10. County average pseudo-DV by 1 µg/m<sup>3</sup> and distribution of individual county pseudo-DVs within each 1 µg/m<sup>3</sup> interval for study counties in Di et al., 2017b. Note: X-axis values of 11 correspond to county average pseudo-DVs from 11.0 to 12.0 µg/m<sup>3</sup>. Thus, x-axis values of 11 or below correspond to pseudo-DVs at or below the level of the current annual standard.**

**Table B-10. County average pseudo-DV by 1  $\mu\text{g}/\text{m}^3$  and distribution of county pseudo-DVs within each 1  $\mu\text{g}/\text{m}^3$  interval for study counties in Di et al., 2017b**

County average pseudo-DV $\text{PM}_{2.5}$ concentration ( $\mu\text{g}/\text{m}^3$ ) interval	Count (percent) of pseudo-DV's $\leq 12.04 \mu\text{g}/\text{m}^3$	Count (percent) of pseudo-DV's $> 12.04 \mu\text{g}/\text{m}^3$

$21.04 < \text{PM}_{2.5} \leq 22.04$	0 (0.00)	11 (100.00)
$22.04 < \text{PM}_{2.5} \leq 23.04$	0 (0.00)	11 (100.00)
Total	3,915 (62.0)	2,400 (38.0)

Figure B-11 and Table B-11 present the relationship between annual pseudo-DVs averaged over the study period and the individual 3-year pseudo-DVs that contribute to those study-period averages for Shi et al. (2016). Of the 116 3-year pseudo-DVs available for this study, 102 (88%) are less than or equal to  $12.04 \mu\text{g}/\text{m}^3$ . Of the counties that have study-period average pseudo-DV's  $\leq 12.04 \mu\text{g}/\text{m}^3$  98.1% of individual 3-year pseudo-DVs are  $\leq 12.04 \mu\text{g}/\text{m}^3$  (i.e., 102 of 104 3-year pseudo-DVs).

**Figure B-11. County average pseudo-DV by 1 µg/m<sup>3</sup> and distribution of individual county pseudo-DVs within each 1 µg/m<sup>3</sup> interval for study counties in Shi et al., 2016. Note: X-axis values of 11 correspond to county average pseudo-DVs from 11.0 to 12.0 µg/m<sup>3</sup>. Thus, x-axis values of 11 or below correspond to pseudo-DVs at or below the level of the current annual standard.**

**Table B-11. County average pseudo-DVs by 1  $\mu\text{g}/\text{m}^3$  and distribution of county pseudo-DVs within each 1  $\mu\text{g}/\text{m}^3$  interval for study counties in Shi et al., 2016.**

County average pseudo-DV $\text{PM}_{2.5}$ concentration ( $\mu\text{g}/\text{m}^3$ ) interval	Count (percent) of pseudo-DV's $\leq 12.04 \mu\text{g}/\text{m}^3$	Count (percent) of pseudo-DV's $> 12.04 \mu\text{g}/\text{m}^3$

Baxter et al., 2017	ST	All-cause mortality	77 US Cities	Time Series study (NCHS data)	Average daily monitored PM <sub>2.5</sub> concentration in each city. 2-day moving average (lag 0-1 days) of PM <sub>2.5</sub> conc. Included in the model.	Poisson regression model and meta-regression  In stage 1, ran single city Poisson time-series models; adjusted for temperature and dew point temperature, including variables for previous day temperature, temporal trends, and trends by age. In stage 2, meta-regression with cluster analysis (5 clusters) based on characteristics of residential infiltration.

Citation	Long-term (LT)/Short-term (ST)	Health Endpoint	Geographic Area	Study Design	Exposure Metric	Statistical Analysis Including Confounding Variables Addressed
Bell et al., 2008	ST	CVD HA Age 65+	202 US Counties with populations $\geq 200,000$	Time Series study (MEDICARE enrollees)	Daily monitored PM <sub>2.5</sub> concentrations. Used lag0 PM2.5 in the model.	2-stage Bayesian hierarchical model  In stage 1, adjusted for temperature and dew point temperature, including variables for previous day's conditions, day-of-the-week, temporal trends, and differential temporal trends by age. In stage 2, county-specific estimates were combined, accounting for their statistical uncertainty.

Citation	Long-term (LT)/Short-term (ST)	Health Endpoint	Geographic Area	Study Design	Exposure Metric	Statistical Analysis Including Confounding Variables Addressed
Bell et al., 2014	ST	CVD, Asthma, and COPD HA Age 65+	4 Counties in MA and CT	Time-series study (MEDICARE enrollees)	<p>PM<sub>2.5</sub> Teflon filter samples obtained from CT and MA DEP and used to measure PM<sub>2.5</sub> total mass.</p> <p>Fairfield County (2 monitors): Estimated exposures using population-weighted averaging of values and assigned exposure to the nearest monitor.</p> <p>Exposures were averaged, weighted by each tracts' 2000 census population. For other counties, values from the single monitor within the county were used. Explored various lags and presented lag0 PM<sub>2.5</sub> model.</p>	<p>Log-linear Poisson regression analysis</p> <p>Adjusted for temperature and dew point temperature, including previous day's temperature and dew point temperature, day-of-the-week temporal trends, and region.</p>

Bell et al., 2015	ST	HF HA 65+	213 U.S. Counties	Time-series study (MEDICARE enrollees)	For each county and day, PM <sub>2.5</sub> measurements for monitors within a county were averaged. Explored various lags and presented lag0 PM2.5 model.	2-stage Bayesian hierarchical model  The stage 1 model included county-specific model adjusted for weather (temperature, dew point, previous days' temperature and dew point), day-of-the-week, and temporal trends. In stage 2 county-specific effect estimates were pulled together to present overall association.

Citation	Long-term (LT)/Short-term (ST)	Health Endpoint	Geographic Area	Study Design	Exposure Metric	Statistical Analysis Including Confounding Variables Addressed
Bravo et al., 2017	ST	CVD HA Age 65+	418 U.S. Counties	Time-series study (MEDICARE enrollees)	Exposure estimated from monitoring data and monitors with multiple measurements for the same day and county were averaged. Explored various lags and distributed lags of PM2.5 exposure.	<p>2-stage Bayesian hierarchical model</p> <p>The stage 1 included log-linear Poisson regression models with over-dispersion fit at county-level. Model adjusted for same-day temperature and dew point temperature, 3-day moving average of temperature and dew point temperature, temporal trends in hospitalizations, day-of-the-week, and age. Fitted distributed lag model with multiple lags (0- to 7-day lags) of PM2.5 conc simultaneously in the county-specific model.</p> <p>The stage 2 estimated the association for the entire study area using two-level normal independent sampling estimation with priors thus allowing to combine risk estimates across counties while accounting for within county SE and between-county variability in the true RR.</p>

Bravo et al., 2017	ST	CVD HA Age 65+	708 U.S. Counties	Time-series study (MEDICARE enrollees)	Daily PM <sub>2.5</sub> concentrations estimated at census tracts using the downscaler method. 24-hr county-level PM <sub>2.5</sub> estimates for counties with population > 50,000 were calculated from a population-weighted average of PM <sub>2.5</sub> concentrations predicted by the downscaler at census tracts within each county using 2000 U.S. Census Data. Explored various lags and distributed lags of PM <sub>2.5</sub> exposure.	2-stage Bayesian hierarchical model  The stage 1 included log-linear Poisson regression models with over-dispersion fit at county-level. Model adjusted for same-day temperature and dew point temperature, 3-day moving average of temperature and dew point temperature, temporal trends in hospitalizations, day-of-the-week, and age. Fitted distributed lag model with multiple lags (0- to 7-day lags) of PM <sub>2.5</sub> conc simultaneously in the county-specific model.  The stage 2 estimated the association for the entire study area using two-level normal independent sampling estimation with priors thus allowing to combine risk estimates across counties while accounting for within county SE and between-county variability in the true RR.

Burnett and Goldberg, 2003	ST	All-cause mortality	8 Canadian Cities	Time-series study	Monitored measurements	Generalized additive model (GAM) analysis to generate pooled estimate of air pollution effect among the eight cities.  The model adjusted for day-of-the-week, temporal trends, and weather variables (daily average temperature, daily average relative humidity, and barometric pressure lagged 0 and 1 days).
Burnett et al., 2004	ST	All-cause mortality	12 Canadian Cities	Time-series study (data from Statistics Canada)	Daily summary pollution exposure measurements based on averaging data over all monitors within each city. Various lags and moving average assessed and presented data for lag 1 for PM2.5.	Random-effects regression model.  Adjusted for temporal trends in mortality and effects of weather using humidex index at lag 0 and lag 1 (a measure of combined effect of temperature and humidity)

Citation	Long-term (LT)/Short-term (ST)	Health Endpoint	Geographic Area	Study Design	Exposure Metric	Statistical Analysis Including Confounding Variables Addressed
Crouse et al., 2012	LT	All-cause mortality	11 Canadian Cities	National Cohort study (Subset of Canadian census mortality follow-up study; 43%)	Mean annual concentration from ground-based monitors averaged from 1987-2001. Participants were assigned exposure based on 11 census divisions. Another set of exposure estimate was derived from satellite remote sensing for period 2001-2006. Estimates at grid-level assigned to the cohort members by linking grid to the enumeration area of residence in 1991.	2 different modelling approach. Approach 1: Cox proportional hazards model, and Approach 2: nested, spatial random-effects Cox model with spatial clusters.  Models adjusted for individual-level covariates, urban/rural indicator, and ecological covariates (% unemployed, % without high school diploma, lowest income quintile, and rural/urban indicator).
Dai et al., 2014	ST	All-cause, CVD, and Respiratory mortality	75 U.S. Cities (with available daily mortality data and PM2.5 data for at least 400 days between 2000 and 2006)	Time-series study (NCHS)	Mean daily monitored PM <sub>2.5</sub> concentrations. For cities with more than one sampling site, concentration data were averaged. Average of 2-day lag (lag 0 and 1) PM2.5 used.	Two stage: Stage 1. City-specific season-stratified time-series analysis using Poisson regression in GAM  Model adjusted for 24-hr average temperature from closest weather station to the city center at lag0 and lag1, temporal trends, and day-of-the-week. Stage 2. Multivariate random effects meta-analysis to combined 300 (i.e. 75 cities * 4 seasons) effect estimates to obtain overall association.

Di et al., 2017b	LT	All-cause mortality 65+	US Nationwide	Open Cohort (MEDICARE enrollees)	Artificial neural network that incorporated satellite-based measurements, simulation outputs from a chemical transport model, land-use terms, meteorological data, and other data to predict daily concentrations of PM <sub>2.5</sub> . The neural network was fit with monitored PM <sub>2.5</sub> data and daily PM <sub>2.5</sub> concentrations were predicted for nationwide grids that were 1x1 km. For each calendar year during which a person was at risk of death the annual average PM <sub>2.5</sub> concentration was assigned according to the ZIP Code of the person's residence. As part of a sensitivity analysis, monitored PM <sub>2.5</sub> data was matched with each person in the study within a distance of 50 km of the nearest monitoring site.	Two-pollutant Cox proportional hazards model with generalized estimating equation to account for correlation between ZIP codes.
Di et al., 2017b (< 12 ug/m3)					Analysis restricted to persons-years with	Accounted for individual variables, (sex, race, Medicaid eligibility, and average age at study entry), zip code-level variables (% Hispanic, % Black, median household income, median value of housing, % > 65 living below poverty level, % > 65 with less than high school education, % of owner-occupied housing units, and population density), county-level variables (county-level BMI and % ever smokers), hospital service area-level variables ( % low-density lipoprotein level measured, % glycated hemoglobin level measured, and % >1 ambulatory visits), 32 km <sup>2</sup> gridded weather and 1 km <sup>2</sup> gridded pollution variables (annual average PM <sub>2.5</sub> concentration, annual average temperature, and annual average humidity), monitor level air pollution variables (PM <sub>2.5</sub> monitored data), and a regional dummy variable.

Gharibvand et al., 2016	LT	Lung cancer incidence	US Nationwide	Cohort study (AHSMOG-2 study)	Using monitored PM <sub>2.5</sub> data from 2000-2001, inverse distance weighted interpolations methods, monthly pollution surfaces for PM <sub>2.5</sub> were created. Monthly exposure averages were based on daily PM <sub>2.5</sub> measurements. Participants were assigned monthly exposure based on their baseline residential address.	Cox proportional hazards model  Covariates included sex, race, smoking status, years since participant quit smoking, average number of cigarettes per day during all smoking years, and education level. Additional covariates included calendar time, alcohol consumption, family income, BMI, physical activity, and marital status. 3 variables identified a priori as either as confounders or effect modifiers: hours/day spent outdoors, years of pre-study residence length at enrollment address, and moving distance from enrollment address during follow-up.
Hart et al., 2015 (monitored)	LT	All-cause mortality	US Nationwide	Cohort study (Nurses' Health study)	Calculated monthly average PM <sub>2.5</sub> from the nearest monitoring location for all addresses. Nearest monitor exposures were validated against personal exposures to PM <sub>2.5</sub> of ambient origin.	Cox proportional hazards model.  Information on potential confounders was available every two years (4 years for diet information) and each woman was assigned updated covariate values for each questionnaire cycle. Confounders examined include age, race, region,

Hart et al., 2015 (modeled)	LT	All-cause mortality	US Nationwide	Cohort study (Nurses' Health study)	<p>Spatio-temporal models of PM<sub>2.5</sub> were developed to estimate monthly PM<sub>2.5</sub> exposures at each geocoded questionnaire mailing address. The model was developed using monitored data and included meteorological and GIS-derived covariates, such as urban land use within 1 km, elevation, tract- and county-level population density, distance to the nearest road for road classes A1-A3 and point-source emission density within 7.5 km.</p> <p>Modeled exposures were validated against personal exposures to PM<sub>2.5</sub> of ambient origin.</p> <p>Previous 12-month moving average of exposure either from nearest monitor or spatio-temporal models were assigned to study participants.</p>	<p>season, physical activity, BMI, hypercholesterolemia, family history of MI, smoking history, Current smoking status, diet, SES (education level, occupation of both of the nurses' parents when she was 16, marital status, and husband's education if applicable). Also adjusted for area-level SES (census tract level median income and house value), and long-term temporal trends.</p> <p>Risk set regression calibration for time-varying exposures was used to correct for bias due to exposure measurement error in the hazard ratios of all-cause mortality using the personal exposure validation data.</p>
Ito et al., 2013 <sup>14</sup>	ST	All-cause mortality	150 U.S. cities	Time-series study	24-hr average PM <sub>2.5</sub> mass data in a given city, and when data	Poisson regression analysis

Citation	Long-term (LT)/Short-term (ST)	Health Endpoint	Geographic Area	Study Design	Exposure Metric	Statistical Analysis Including Confounding Variables Addressed
					<p>from multiple monitors were available in a given city, computed the average of the daily values after standardizing each site's data using the mean and standard deviation of the sites data.</p> <p>Pollutant concentration is expressed in the model as a deviation from the monthly mean to reduce the influence of the seasonal cycles of the pollutants on the overall associations and help focus on the short-term associations.</p>	<p>First city- and season-specific Poisson regression was run, and then city-specific estimates were combined using random effects approach</p> <p>Adjusted for temporal trends (annual cycles and influenza epidemics), immediate and delayed temperature, and day-of-week pattern, for entire years (2001-2006) and for warm (April-September) and cold (October-March) seasons.</p> <p>In second stage, assessed effect modification using land-use variables and average air pollution levels.</p>

<sup>14</sup> This study is not referenced individually in the ISA, but is study 3 of the National Particle Component Toxicity (NPACT) Initiative published in HEI (Lippmann et al., 2013).

Kloog et al., 2014	ST	CVD and COPD HA Age 65+	7 U.S. Mid-Atlantic States and D.C.	Case-crossover design (MEDICARE enrollees)	Spatiotemporal model: Used day-specific calibrations of aerosol optical depth (AOD) data, using ground PM <sub>2.5</sub> measurements. Incorporated land use regression (elevation, distance to major roads, percent of open space, point emissions and area emissions) and meteorological variables (temperature, wind speed, relative humidity and visibility). Model used to predict daily PM <sub>2.5</sub> concentrations at a 10 x 10 km spatial resolution. Daily predicted PM <sub>2.5</sub> exposure estimates were matched to zip codes.	Conditional logistic regression analysis  Temperature with the same moving average as PM <sub>2.5</sub> was included in the model as a potential confounder. Study design samples only cases and compares each subject's exposure experience in a time period just before a case-defining event with the subject's exposure at other times, eliminating confounding (unmeasured or measured) that do not vary over time. Cases were matched on day of the week and defined the relevant exposure time window as the mean exposure of the day of and day before the patient's hospital admission. Effect modification: 1) assessed whether subject residence within 30 km of a monitor or farther modified the PM <sub>2.5</sub> association; 2) examined interaction between exposure and income level and gender.

Shi et al., 2016	ST and LT	Total mortality (65+)	New England Area with 6 U.S. States	Open Cohort study (MEDICARE enrollees)	Daily PM <sub>2.5</sub> was predicted at 1-km <sup>2</sup> spatial resolution from novel 3-stage statistical models. Similar 3-stage approach was used to estimate daily temperature. Participants were assigned 365-day moving average (for long-term exposure) and average lag0-1 (for short-term exposure) based on the ZIP codes of residence.	Chronic effects of air pollution assessed using Cox proportional hazard models. Acute effects of air pollution assessed using Poisson log-linear models. Both acute and chronic effects were assessed using Poisson survival analysis. Analysis performed in full-cohort as well as low exposure cohorts.  Poisson survival models were adjusted for smooth function of time, temporal covariates such as temperatures and day of the week, spatial covariates such as zip code-level socio-economic variables.
Stieb et al., 2009	ST	Cardiac and Respiratory ED visits	Seven Canadian Cities	Time series study (Hospital cases)	PM Data from National Air Pollution Surveillance (NAPS) system. City averages of the exposure were calculated by averaging stations within the city. Calculated average concentration for lag0-2.	Generalized Linear Models with natural spline functions of time to adjust for seasonal cycles in air pollution and health  Confounders included: Mean daily temperature and relative humidity at lag 0, 1, and 2 days, day of the week and holidays.

Szyszkowicz, 2009	ST	Angina ED	Seven Canadian Cities	Time series study (Hospital cases)	PM Data from National Air Pollution Surveillance (NAPS) system. City averages of the exposure were calculated by averaging stations within the city. Calculated average concentration for lag0-2.	Generalized Linear Mixed models  Models adjusted for meteorological variables such as relative humidity, temperature and atmospheric pressure (a daily 24-hr average measurements were calculated). Temperature and relative humidity in models were represented by natural splines. Stratified analysis by season as well as combined for the whole period.
Thurston et al., 2016a	LT	All-cause, CVD and respiratory mortality	6 U.S. States and 2 MSAs	Cohort study (NIH_AARP cohort)	PM Data from US EPA AQS. Census-tract estimates generated using hybrid LUR and BME models that were combined to generate monthly estimates of PM2.5.  Participants exposure was estimated at census-tract of residence and included annual mean concentration in the year of mortality, and 1-year lag average.	Cox proportional hazard models  Stratified analysis by age, sex, regions (6 states and 2 MSAs). Confounders adjusted included: race, education, marital status, BMI, alcohol consumption, smoking history, contextual variables such as median household income and % pop with less than high school education. Several interactions between PM2.5 and socio-demographics were also tested.

Turner et al., 2016	LT	Lung cancer mortality (30+)	U.S. Nationwide	Cohort study (ACS Cancer Prevention Study II)	Estimated PM <sub>2.5</sub> concentrations were obtained using a national-level hybrid land use regression (LUR) and Bayesian maximum entropy (BME) interpolation model. Monthly PM <sub>2.5</sub> monitoring data were collected from 1,464 sites from 1999 through 2008, with 10% reserved for cross- validation. The base LUR model that predicted PM <sub>2.5</sub> concentrations included traffic within 1 km and green space within 100 m <sup>3</sup> . Residual spatiotemporal variation in PM <sub>2.5</sub> concentrations was interpolated with a BME interpolation model. The two estimates were then combined. The cross validation R <sup>2</sup> was approximately 0.79. Mean PM <sub>2.5</sub> (1999–2004) concentrations were used here.	Cox proportional hazards model  Models were adjusted for education; marital status; BMI and BMI squared; cigarette smoking status; cigarettes per day and cigarettes per day squared; years smoked and years smoked squared; started smoking at younger than 18 years of age; passive smoking (hours); vegetable, fruit, fiber, and fat intake; beer, wine, and liquor consumption; occupational exposures; an occupational dirtiness index; and six sociodemographic ecological covariates at both the postal code and postal code minus county-level mean derived from the 1990 U.S. Census (median household income and percentage of African American residents, Hispanic residents, adults with postsecondary education, unemployment, and poverty).  Potential confounding examined by elevation, MSA size, annual average daily maximum air temperature, mean county-level residential radon concentrations, and 1980 percentage of air conditioning.

This appendix provides supplemental information related to the risk assessment described in section 3.3 of final particulate matter (PM) policy assessment (PA), including:

- Additional technical detail on the risk assessment approach, including sources and derivation of key inputs to the risk modeling process (section C.1).
- Supplemental risk results (section C.2) intended to provide additional context for the summary risk estimates presented in the PA section 3.3.2, including:
  - The modeled risk estimates that underly summary tables presented in PA section 3.3.2 aggregated to the CBSA-level (i.e., the urban study area) (section C.2.1).
  - Additional graphics including line plots, maps and scatter plots illustrating the distribution of the grid-level risk estimates (section C.2.2).
- Characterization of variability and uncertainty related to the risk assessment (section C.3).

## **C.1 ADDITIONAL TECHNICAL DETAIL ON THE RISK ASSESSMENT APPROACH**

As discussed in section 3.3 of the PM PA, our general approach to estimating PM<sub>2.5</sub>-associated human health risks in this review utilizes concentration-response (CR) functions obtained from epidemiology studies to link ambient PM<sub>2.5</sub> exposure to risk in the form of incidence (counts) of specific health effects. The derivation and use of this type of CR function in modeling PM<sub>2.5</sub>-attributable risk is well documented both in previous PM NAAQS-related risk assessments (section 3.1.2 of U.S. EPA, 2010) and in Section C.1.1 of this appendix. Inputs required to model risk using these CR functions are identified below (Figure C-1) and include (a) the concentration-response (CR) functions themselves, which are obtained from epidemiologic studies (section C.1.1), (b) baseline health incidence data and information on population demographics (section C.1.2), and (c) modeled ambient PM<sub>2.5</sub> concentrations corresponding to air quality scenarios of interest (section C.1.5).

**Figure C-1. Key inputs to the risk assessment**

### **C.1.1 Selection of Key Health Endpoints and Specification of Concentration-Response Functions from Epidemiologic Studies**

In selecting specific CR functions for the risk assessment, we focus on health outcomes for which the PM ISA determines the evidence supports either a “causal” or a “likely to be causal” relationship with short- or long-term PM<sub>2.5</sub> exposures (U.S. EPA, 2019). As discussed in Chapter 3 of this final PA (Table 3-1), these outcomes include the following:

- mortality (resulting from long- and short-term exposure),
- cardiovascular effects (resulting from long- and short-term exposure),
- respiratory effects (resulting from long- and short-term exposure),
- cancer (resulting from long-term exposure), and
- nervous system effects (resulting from long-term exposure).

We have focused the analysis on short- and long-term PM exposure-related mortality, reflecting its clear public health importance, the large number of epidemiologic studies available for consideration, and the broad availability of baseline incidence data. The specific set of health effect endpoints included in the risk assessment are:

- *Long-term PM exposure-related mortality*: all-cause, ischemic heart disease (IHD) related, lung-cancer related

- *Short-term PM exposure-related mortality:* all-cause/non-accidental

To identify specific epidemiologic studies for potential inclusion in the risk assessment, we focus on U.S. multicity studies assessed in the ISA. These studies are identified in section 3.2.3.2.1 of this PA (Figures 3-3 to 3-6). Of these, we used the following criteria to identify the specific set of studies for inclusion in the risk assessment:

- *National-scale coverage:* We focus on epidemiology studies reporting national-level effect estimates. Epidemiology studies that focus on individual cities or regions were excluded. Focusing on national-level epidemiological studies has the benefit of characterizing PM<sub>2.5</sub>-associated risks broadly across the U.S. and in relatively large populations (compared with single-city or regional studies), which tends to improve precision in the effect estimated generated.
- *Evaluation of relatively lower ambient PM concentrations:* In selecting epidemiology studies, to the extent possible, we favored those studies which characterized the ambient PM<sub>2.5</sub>-mortality relationship at levels at or near the current NAAQS, given that the risk assessment would be focusing on evaluating risk associated with the current NAAQS.
- *Populations with available baseline incidence data:* For some populations (e.g., diesel truck drivers), it can be challenging to model risk at the national-level given uncertainties associated with specifying key inputs for risk modeling (i.e., baseline incidence rates for mortality endpoints and detailed national-level demographics). For that reason, we favored those epidemiology studies providing effect estimates for populations readily generalizable to the broader U.S. population (e.g., specific age groups not differentiated by additional socio-economic, or employment attributes).
- *Estimates of long-term PM<sub>2.5</sub> exposures based on hybrid modeling approaches:* For long-term PM<sub>2.5</sub> exposures, we focus on epidemiologic studies that estimate exposures with hybrid modeling approaches. The primary rationale for this decision is the agreement between the design of these epidemiology studies (i.e., their use of hybrid-based modeling approaches in characterizing ambient PM) and the hybrid air quality surfaces we are using in this risk assessment. This general agreement between the air modeling surfaces used in long-term mortality epidemiology studies and our air quality modeling reduces uncertainty in the risk assessment.
- *Estimates of short-term PM<sub>2.5</sub> exposures based on composite monitor data:* Short-term mortality epidemiology studies utilizing hybrid modeling approaches, which are fewer in number compared with long-term mortality studies, tend to be regional in scope and consequently, did not meet the criterion of providing national-scale effect estimates. For that reason, in modeling short-term mortality, epidemiology studies utilizing composite-monitor based exposure surrogates were used as the basis for deriving CR functions. We recognize the uncertainty introduced into the modeling of short-term mortality due to the use of effect estimated obtained from studies utilizing composite monitors. However, we

felt these use of national-scale epidemiology studies was a more important criterion for selection.<sup>1</sup>

- *Evaluation of potential confounders and effect modifiers:* Preference was given, to the extent possible, to those studies which more fully address potential confounders and effect modifiers and to those studies which utilize individual- rather than ecological measures in representing those confounders/effect modifiers. Recognizing that both single- and multi-pollutant models have advantages and disadvantages in characterizing the ambient PM-mortality relationship, to the extent possible, we include epidemiology studies (and associated effect estimates) based on both single- and multi-pollutant models.
- *Exploration of multiple approaches for estimating exposures:* For studies that estimate PM<sub>2.5</sub> exposures using hybrid modeling approaches, preference was given to studies that also explore additional methods for estimating exposures (i.e., multiple hybrid methods or hybrid methods plus monitor-based methods) and compare health effect associations across approaches.

Application of the criteria listed above resulted in the selection of the epidemiology studies presented in Table C-1 for inclusion in the risk assessment as sources of effect estimates. Table C-1 includes summary information on study design, details on the selection of effect estimates, the derivation of beta values, and specification of CR functional form based on those effect estimates for use in the risk assessment. The procedure used to derive CR functions (including specification of the beta values and mathematical forms for those functions) is described below.

The remainder of this section describes the method used in specifying the concentration-response (CR) functions used in the PM NAAQS REA (information presented in this section is drawn from BenMAP Manual, Appendix C with additional detail specific to the epidemiology studies selected for use in this risk assessment).<sup>2</sup> These CR functions translate changes in ambient PM<sub>2.5</sub> into changes in baseline incidence rates for specific disease endpoints utilizing beta ( $\beta$ ) values obtained from epidemiology studies studying the association between ambient PM<sub>2.5</sub> exposure and specific health endpoints. These beta values (and associated standard errors) are based on effect estimates obtained from the underlying epidemiology studies (equation below). In addition, the mathematical forms for the health impact functions specified for use in

---

<sup>1</sup>After identifying studies for inclusion in the draft risk assessment and initiating analyses, we became aware that Di et al., 2017a uses a hybrid model-based approach to estimate PM<sub>2.5</sub> exposures. The primary effect estimate reported for this study (which reflects copollutant modeling including ozone) is larger than effect estimates selected for this risk assessment. Specifically, the copollutant model for Di et al., 2017a reports an increased daily mortality risk of 1.05% (95<sup>th</sup> CI: 0.95-1.15%) with this effect estimate being two to three times larger than similar effect estimates used in this risk assessment and has a substantially tighter confidence interval (Table C-1). Given the approximate linearity of the CR functions used, we anticipate that this difference in effect estimate would translate into a similar magnitude of difference in modeled mortality incidence (i.e., 2-3 times higher had the Di et al., 2017a effect estimate been used in the risk assessment).

<sup>2</sup> <https://www.epa.gov/benmap/benmap-ce-manual-and-appendices>

this risk assessment reflect the models used in the epidemiology studies providing those effect estimates. Consequently, derivation of the beta values based on effect estimates from underlying epidemiology studies (and specification of the form of the health impact functions) represents a key step in the design of the REA.

The majority of the epidemiology studies providing effect estimates for this PM REA utilized either Poisson or Cox proportional hazard models which result in exponential (or log-linear) forms for the CR functions, where the natural logarithm of mortality incidence is a linear function of PM<sub>2.5</sub>.<sup>3</sup> If we let  $x_0$  denote the baseline (starting) PM<sub>2.5</sub> level, and  $x_1$  denote the control (ending ) PM<sub>2.5</sub> level,  $y_0$  denote the baseline incidences rate of the health effect, and Pop the underlying population count for the applicable demographic group in the spatial unit of analysis<sup>4</sup> we can derive the following CR function specifying the relationship between the change in  $x$ ,  $\Delta x = (x_0 - x_1)$  and the corresponding change in  $y$ ,  $\Delta y$  (mortality incidence):

$$\Delta y = y_0 [1 - e^{-\beta \Delta x}] * \text{Pop}$$

Given that the epidemiology studies providing effect estimates for long-term exposure-related mortality and short-term exposure-related mortality in the context of the current PM REA (Table C-1) use different categories of models (Cox proportional hazard and Poisson/Logistic, respectively) we describe the process of deriving the betas and specifying CR functional forms separately for each of these endpoint categories. As noted earlier, the logit model utilized in Zanobetti et al., 2014, is discussed at the end of the section covering short-term PM<sub>2.5</sub>-related mortality.

#### Derivation of betas for long-term PM<sub>2.5</sub> exposure-related mortality

Cox proportional hazard models used to evaluate mortality associated with long-term PM<sub>2.5</sub> exposure are designed to model effects on population survival. This class of epidemiology model is based on a hazard function, defined as the probability that an individual die at time  $t$ , conditional on that individual having survived up to time  $t$ . As such, the hazard function represents a time-specific snapshot of the rate of mortality (events per unit time) within a study population. While the risk can vary over time, in the case of the Cox proportional hazard model, it is assumed that the hazard ratio is constant. The proportional hazard model takes the form:

---

<sup>3</sup> One study. Zanobetti et al., 2014, supporting the modeling of short-term PM<sub>2.5</sub> exposure-related mortality provided a logistic-based model form, which is discussed at the end of this section.

<sup>4</sup> Spatial unit of analysis refers to the geographic scale at which the CR function is applied in generating a risk (incidence) estimate (e.g., zip code, county, 12km grid cell). Typically, the spatial unit of analysis used in a REA is based on the spatial scale reflected in the epidemiology study(s) supplying the effect estimates. For this REA, the spatial unit of analysis is the 12km grid cell.

$$h(X, t) = h_0(t)e^{X \cdot \beta} ,$$

Where X is a vector of explanatory variables,  $\beta$  is a vector of associated coefficients and  $h_0(t)$  is the baseline hazard (the risk when all covariates (X) are set to zero).

Epidemiology studies utilizing the Cox proportional hazard model in characterizing ambient PM<sub>2.5</sub>-health effects typically report hazard ratios (HRs) as the effect estimate. HRs represent the ratio of hazard functions for the baseline and control scenarios reflecting a specific difference in ambient PM<sub>2.5</sub> exposure (typically a 10 ug/m<sup>3</sup> increment). The HR simplifies as shown (with the baseline hazard ratio dropping out), allowing us to readily derive the Beta value from this effect estimate:

$$HR = \frac{h(X_0, t)}{h(X_c, t)} = \frac{h_0(t)e^{X_0 \cdot \beta}}{h_0(t)e^{X_c \cdot \beta}} = e^{\Delta PM \cdot \beta}$$

It is then possible to calculate the beta as follows:

$$\beta = \frac{\ln(HR)}{\Delta PM}$$

As noted in Sutradhar and Austin, 2018, the HR associated with a Cox-proportional hazard model may approximate the RR when the effect estimate (and consequently the beta) is relatively small. This is the case with the effect on mortality modeled for long-term exposure to ambient PM<sub>2.5</sub> (i.e., the size of the effect estimate supports an assumed equivalency between HR and RR). The near equivalency between the HR and RR, allows us to utilize the beta derived above in a CR-function based on a log-linear functional form of the type presented earlier, to model changes in mortality related to changes in ambient PM.

#### Derivation of betas for short-term PM<sub>2.5</sub> exposure-related mortality

The epidemiology studies selected for use in modeling short-term PM<sub>2.5</sub> exposure-related mortality utilize both the Poisson (log-linear) model form (Baxter et al., 2017) and the logit model form (Zanobetti et al., 2014).<sup>5</sup> In both cases, the epidemiology studies provide effects in terms of *percent increase* in mortality.

The log-linear (Poisson) model is used to evaluate effects associated with continuous (count) events. With the log-linear (Poisson) model, the relative risk is simply the ratio of the two risks:

---

<sup>5</sup> Note that the Ito et al., 2013 study also utilizes a Poisson model. However, that study provides beta values (including standard errors) and for that reason the results of this study are directly applicable in modeling changes in mortality without any of the derivations presented here for the other studies.

$$RR = \frac{y_0}{y_c} = e^{\beta \cdot \Delta PM}$$

The derivation of the beta with a Poisson model specified RR is as follows. Taking the natural log of both sides, the beta coefficient in the CR function underlying the relative risk can be derived as:

$$\beta = \frac{\ln(RR)}{\Delta PM}$$

The beta derived in this fashion can then be used with a log-linear functional form (as presented earlier) to model changes in mortality related to changes in ambient PM.

The logistic model form is used to model dichotomous events. With the logistic model form, when we are provided with a RR value, as is the case here, we can make a similar assumption to that used above with the Cox proportional hazard function (i.e., that the OR and RR approach equivalency under conditions of relatively small effect levels). That observation in turn allows us to assume that

$$RR = \frac{y_0}{y_c} = (1 - y_0) \times e^{-\Delta PM \cdot \beta} + y_0$$

Then, assuming (based on the relatively small size of the baseline incidence) that:

$$e^{-\Delta PM \cdot \beta} \cong (1 - y_0) \times e^{-\Delta PM \cdot \beta} + y_0$$

$$\Rightarrow RR \cong e^{-\Delta PM \cdot \beta}$$

It is then possible to calculate the underlying beta coefficient as follows:

$$\frac{\ln(RR)}{-\Delta PM} \cong \beta$$

Since the derivation of the beta is based on the assumption of a log linear functional form, we can apply the beta in a log-liner CR function of the form described earlier:

$$\Delta y = y_0[1 - e^{-\beta \Delta x}] * \text{Pop}$$

**Table C-1. Details regarding selection of epidemiology studies and specification of concentration-response functions for the risk assessment.**

Reference and study title	Study description	Exposure Estimation Approach	CR function model	Location of study effect estimate(s) in journal article	Additional notes regarding effect estimate selection	Epi-demio-logic statistic	Mortality endpoint	Selected effect estimate	Selected beta	Selected beta standard error (SE)
<b>Long-term exposure-related mortality studies</b>										
Di et al., 2017b  Air Pollution and Mortality in the Medicare Population	Exploring relationship between air pollution (ozone, PM <sub>2.5</sub> ) and mortality Key details: - Medicare population (65+) - ecological control for confounders - all-cause mortality only - provides CR function slopes for areas above and below the current PM NAAQS level (but model for areas below current standard only done for low ozone cells)	Exposures estimated at zip code of residence based on a neural network model that incorporates satellite data, chemical transport modeling, land-use terms, meteorology data, monitoring data, and other data	Cox proportional-hazards model with a generalized estimating equation to account for the correlation between ZIP codes	Table 2 Risk of death associated with an increase of 10 µg/m <sup>3</sup> PM <sub>2.5</sub> or an increase of 10 ppb in ozone concentration. Uses single pollutant model for full analysis.	Using single pollutant, full PM range model (model for <12 µg/m <sup>3</sup> applicable to only low-ozone days) <sup>6</sup>	Hazard ratio (95 percent CI)	All-cause	1.084 (1.081-1.086)	8.07E-03	1.18E-04
Jerrett et al., 2016  Comparing the Health Effects of Ambient Particulate Matter Estimated Using Ground-Based Versus Remote Sensing Exposure Estimates	Compares mortality effect estimates for PM <sub>2.5</sub> modeled from remote sensing to those for PM <sub>2.5</sub> modeled using ground-level information. - ACS cohort (Ages 30+) - IHD and diseases of circulatory system - individual-level confounder control	Multiple exposure estimation approaches evaluated – risk assessment uses results based on an ensemble approach that incorporates chemical transport modeling, land use data, satellite data, and data from ground-based monitors	Cox proportional hazard model	Table 4 IHD, fully adjusted (1990 ecological confounders) ensemble estimate	Used the ensemble estimate (pools effect estimates generated using different exposure estimates)	Hazard ratio (95 percent CI)	IHD	1.15 (1.11-1.19)	1.40E-02	1.78E-03

<sup>6</sup> We note that Di et al., 2017b does include a copollutant model-based effect estimate (HR 1.073, 95<sup>th</sup>%CI 1.071-1.075). Had this effect estimate been used in risk modeling (which would translate into a beta value of 7.05E-3), we would anticipate the risk estimates for all-cause mortality to be slightly less (~13% lower based on comparison of calculated betas) than those estimated based on the single-pollutant model used in this risk assessment.

### C.1.2 Specification of Demographic and Baseline Incidence Data Inputs

This risk analysis requires both demographic and baseline-incidence data for the mortality endpoint categories evaluated. For our analyses, these data are projected to the year 2015 since the hybrid surfaces included in the analyses are based on a 2015 model year<sup>7</sup>. The BenMAP-CE model<sup>8</sup> is used in this risk assessment and the relevant demographic and baseline incidence data for the contiguous U.S., from the sources described below, is readily available within the current version of BenMAP-CE:

- *Demographic data:* BenMAP-CE includes 2010 U.S. Census block-level age, race, ethnicity and gender-differentiated data which the program can aggregate to various grid-level definitions selected by the user, including the 12 km grid coverage used for risk modeling in this analysis. In addition, BenMAP-CE has the ability to project future demographics using county-level projections provided by Woods & Poole (2015). See BenMAP-CE manual Appendix J for additional detail.<sup>9</sup>
- *Baseline incidence data for mortality endpoints:* County-level mortality and population data from 2012-2014 for seven causes of death in the contiguous U.S. was obtained from the Centers for Disease Control (CDC) WONDER database. To estimate values for 2015, we applied annual adjustment factors, based on a series of Census Bureau projected national mortality rates for all-cause mortality. See BenMAP-CE manual Appendix D for additional detail.<sup>9</sup>

### C.1.3 Study Area Selection

In selecting U.S. study areas for inclusion in the risk assessment, we focus on the following characteristics:

- *Available ambient monitors:* We focus on areas with relatively dense ambient monitoring networks, where we have greater confidence in adjustments to modeled air quality concentrations in order to simulate “just meeting” the current and alternative primary PM<sub>2.5</sub> standards (air quality adjustments are described below in section C.1.4).
- *Geographical Diversity:* We focus on areas that represent a variety of regions across the U.S. and that include a substantial portion of the U.S. population.
- *PM<sub>2.5</sub> air quality concentrations:* We balance the value of including a broad array of study areas from across the U.S. against the larger uncertainty associated with air quality adjustments in certain areas. For example, many areas have recent air quality that meets the current primary PM<sub>2.5</sub> standards. Inclusion of such areas in the risk assessment necessitates an upward adjustment to PM<sub>2.5</sub> air quality concentrations in order to simulate

---

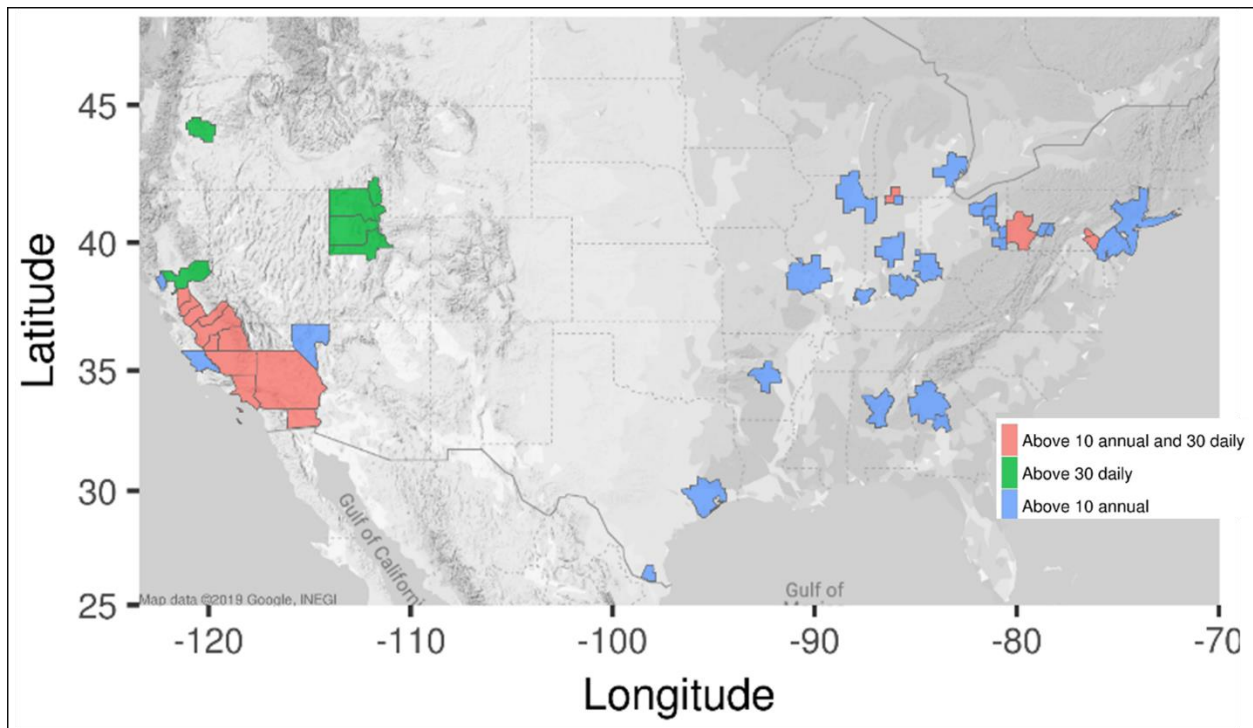

<sup>7</sup> The 2015 model year was the most recent CMAQ modeling platform available at the time of the design of the risk assessment and represents the central year of the 2014-2016 design value (DV) period. A single modeling year was used in the risk assessment, rather than modeling risk for the full three-year design value period, because model inputs for the 2016 period were not available at the time of the study (section C.1.4.3).

<sup>8</sup> <https://www.epa.gov/benmap>

<sup>9</sup> <https://www.epa.gov/benmap/benmap-ce-manual-and-appendices>

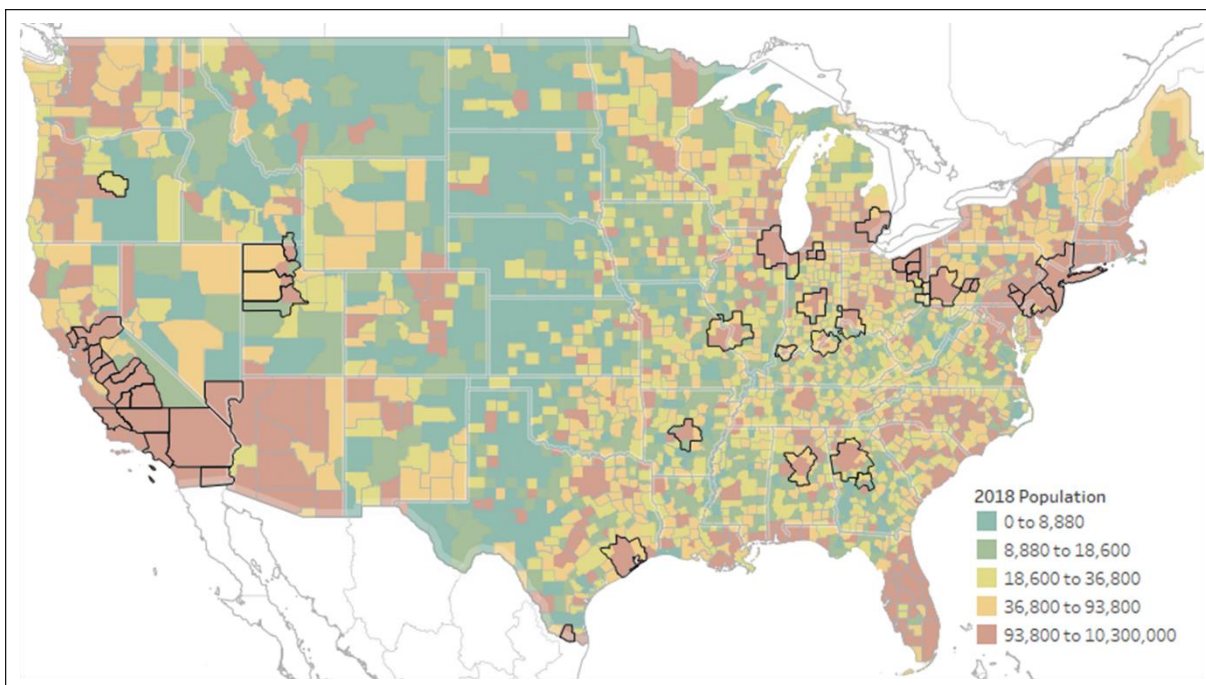

just meeting the current standards. Given uncertainty in how such increases could potentially occur, we select areas requiring either a downward adjustment to air quality or a relatively modest upward adjustment (i.e., no more than  $2.0 \mu\text{g}/\text{m}^3$  for the annual standard and  $5 \mu\text{g}/\text{m}^3$  for the 24-hour standard). In addition, as discussed further in section C.1.4.2, we excluded several areas that appeared to be strongly influenced by exceptional events.

Applying these criteria resulted in the inclusion of 47 core-based statistical areas (CBSAs) as study areas. These 47 study areas are identified in Figure C-2, with colors indicating whether they meet either or both the design value cutoffs. Green indicates areas that only exceed a 24-hr design value of  $30 \mu\text{g}/\text{m}^3$ , blue indicates areas that only exceed an annual design value of  $10 \mu\text{g}/\text{m}^3$ , and red indicates areas that exceed both cutoffs.

**Figure C-2. Map of the areas modeled in the risk assessment, colored by 2014-2016 PM<sub>2.5</sub> design values (DV).**

These 47 urban study areas include many highly populated CBSAs (Figure C-3 and Figure C-4). The population at or above the age of 30 in these areas includes roughly 58.4 million people, or approximately one-quarter of the total U.S. population above that age. Additional age-specific population information can be found in Table C-2.

**Figure C-3. Map of the 2018 U.S. population by CBSA, with the selected urban study areas outlined.**

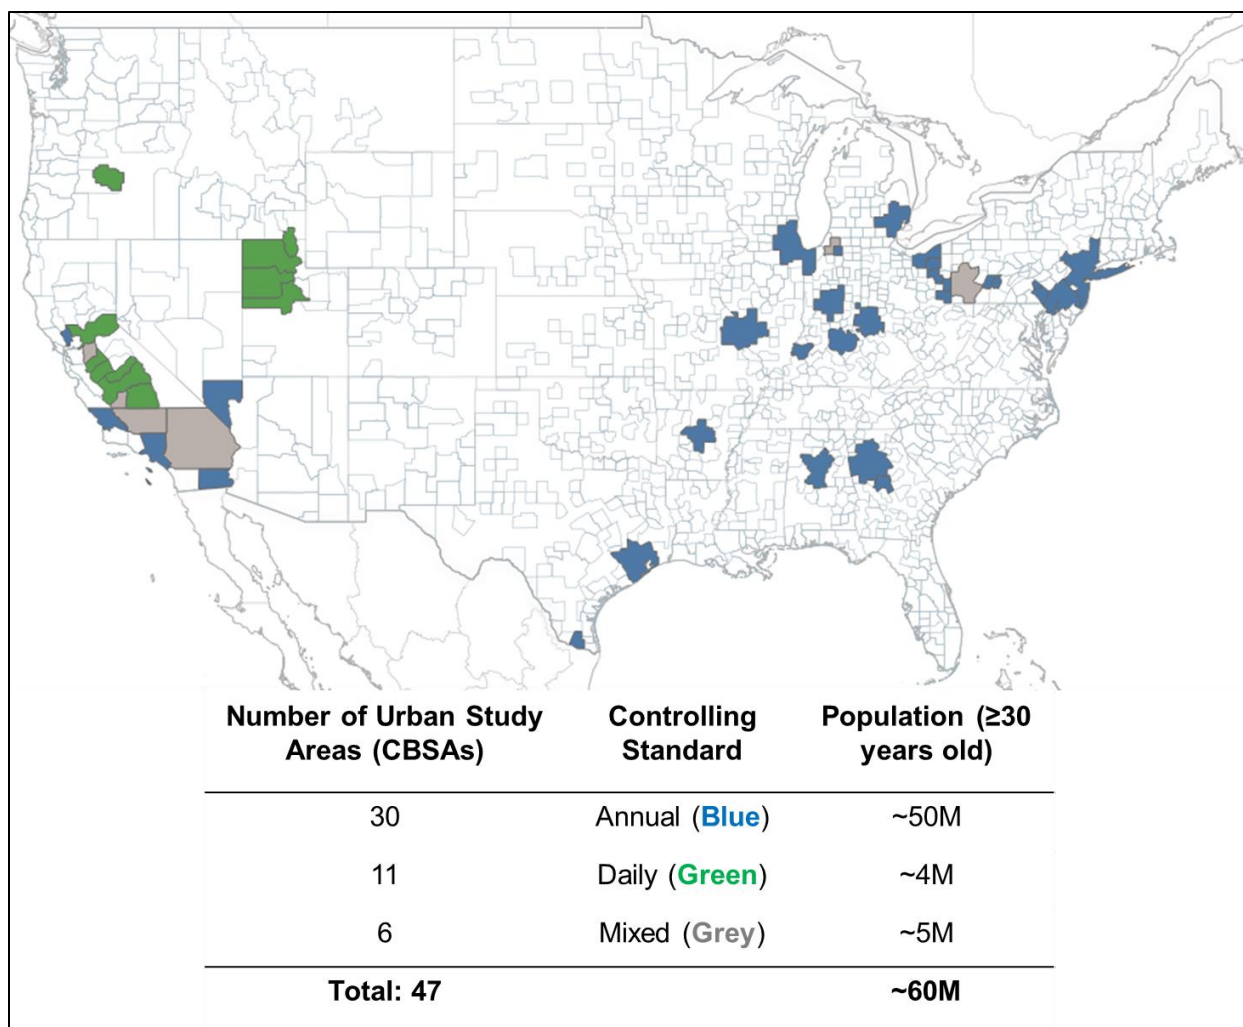

**Figure C-4. Population counts for ages 30 and above from each of the 47 CBSAs included in the risk assessment.**

**Table C-2. Population of the 47 urban study areas stratified by age.**

Population Age Range (Years)	Study Area Groupings (Millions)		
	47	30 (Annual-Controlled)	11 (24-hr-Controlled)
0-99	98.5	82.5	7.2
30-99	58.4	49.5	3.9
65-99	13.2	11.1	0.8
55-85	23.5	19.9	1.5

As noted in section 3.3 of this final PA and illustrated in Figure C-5, the 47 urban study areas include 30 study areas where just meeting the simulated standards is controlled by the current annual standard ( $12 \mu\text{g}/\text{m}^3$ ), 11 study areas where just meeting the simulated standards is controlled by the current 24-hr standard ( $35 \mu\text{g}/\text{m}^3$ ), and 6 study areas where just meeting the simulated standards is controlled by either the annual or 24-hr standard, depending on the air quality scenario and adjustment strategy (discussed more fully in section C.1.4).

**Figure C-5. Map of 47 Urban Study Areas Reflected in Risk Modeling Identifying Subsets Reflected in Risk Modeling (population estimates in millions of people).**

#### **C.1.4 Generation of Air Quality Inputs to the Risk Assessment**

As described in detail below, air quality modeling was used to develop gridded  $PM_{2.5}$  concentration fields for the risk assessment. A  $PM_{2.5}$  concentration field for 2015 was developed using a Bayesian statistical model that calibrates chemical transport model (CTM) predictions of  $PM_{2.5}$  to surface measurements (Chapter 2, section 2.3.3). The 2015  $PM_{2.5}$  concentration field was then adjusted to correspond to just meeting the existing and potential alternative standards using response factors developed from CTM modeling with emission changes relative to 2015. The modeling approach applies realistic spatial response patterns from CTM modeling to a concentration field, similar to those used in a number of recent epidemiologic studies, to characterize  $PM_{2.5}$  fields at 12 km resolution for study areas.

The adjustments to simulate just meeting the current standards and alternative standards are approximations of these air quality scenarios. In reality, changes in PM<sub>2.5</sub> in an area will depend on what emissions changes occur and the concentration gradients of PM<sub>2.5</sub> will vary across an area accordingly. For our analyses, two different adjustment approaches were applied to provide two outcomes that could represent potential bounding scenarios of PM<sub>2.5</sub> concentrations changes across the study area. The two adjustment approaches used to guide the generation of these modeled surfaces were:

- *Primary PM-based modeling approach (Pri-PM)*: This modeling approach simulates air quality scenarios of interest by preferentially adjusting direct (i.e., primary, directly-emitted) PM emissions. As such, the changes in PM<sub>2.5</sub> tend to be more localized near the direct emissions sources of PM. In locations for which air quality scenarios cannot be simulated by adjusting modeled primary emissions alone, SO<sub>2</sub> and NO<sub>x</sub> precursor emissions are additionally adjusted to simulate changes in secondarily formed PM<sub>2.5</sub>.
- *Secondary PM-based modeling approach (Sec-PM)*: This modeling approach simulates air quality scenarios of interest by preferentially adjusting SO<sub>2</sub> and NO<sub>x</sub> precursor emissions to simulate changes in secondarily formed PM<sub>2.5</sub>. In this case, the reductions in PM<sub>2.5</sub> tend to be more evenly spread across a study area. In locations for which air quality scenarios cannot be simulated by adjusting precursor emissions alone, a proportional adjustment of air quality is subsequently applied.

The air quality surfaces generated using these two approaches are not additive. Rather, they should be viewed as reflecting two different broad strategies for adjusting ambient PM<sub>2.5</sub> levels.

In addition, we also employed linear interpolation and extrapolation to simulate air quality under two additional alternative annual standard levels, 11.0 and 9.0 µg/m<sup>3</sup>, respectively (section 3.3.1 of the PA, Figure 3-11). Interpolation and extrapolation were only performed for grid cells in the subset of 30 urban study areas where the annual standard was controlling in both Pri-PM and Sec-PM simulated air quality scenarios of both 12/35 and 10/30 standard combinations. The interpolation and extrapolation were completed at the grid-cell level based on values simulated using hybrid air quality modeling to just meet the current annual standard of 12.0 µg/m<sup>3</sup> and alternative annual standard of 10.0 µg/m<sup>3</sup> (section 3.3.1 of the PA, Figure 3-11). A similar linear extrapolation/interpolation was not conducted for additional 24-hr standards due to the weaker relationship between the 98<sup>th</sup> percentile of 24-hr PM<sub>2.5</sub> concentrations, which are most relevant for simulating air quality that just meets the 24-hour standard, and the concentrations comprising the middle portion of the PM<sub>2.5</sub> air quality distribution, which are most relevant for estimating risks based on information from epidemiologic studies (i.e., discussed further in sections 3.1.2 and 3.2.3.2 in the PA).

The sections below provide more detailed information on the air quality modeling approach used to adjust air quality to simulate just meeting the current or alternative primary

PM<sub>2.5</sub> standards. Tables containing PM<sub>2.5</sub> DVs for the air quality projections can be found in section C.4.

#### **C.1.4.1 Overview of the Air Quality Modeling Approach**

To inform risk calculations, recent PM<sub>2.5</sub> measurements were analyzed to characterize the magnitude and spatial distribution of PM<sub>2.5</sub> concentrations. These data were then coupled with air quality modeling data to project ambient air quality levels corresponding to just meeting the existing and alternative PM<sub>2.5</sub> NAAQS<sup>10</sup> in specific areas. An overview of the approach is provided in Figure C-6. The process starts by acquiring PM<sub>2.5</sub> monitoring data from EPA's Air Quality System (AQS)<sup>11</sup> and simulating PM<sub>2.5</sub> concentrations with the Community Multiscale Air Quality (CMAQ)<sup>12</sup> model for base case and emission-sensitivity scenarios (Figure C-6, Box 1). The monitored and modeled data are then fused using the Downscaler model and the Software for Model Attainment Test-Community Edition (SMAT-CE)<sup>13</sup> to develop a baseline spatial field of PM<sub>2.5</sub> concentrations and relative response factors (RRFs) for projecting PM<sub>2.5</sub> concentrations, respectively (Figure C-6, Box 2). PM<sub>2.5</sub> concentrations are projected in two main steps using output from Downscaler and SMAT-CE (Figure C-6, Box 3). First, the PM<sub>2.5</sub> concentrations measured at monitoring sites in an area are iteratively projected using the RRFs to identify the percent change in anthropogenic emissions required for the highest monitored DV in the area to just meet the controlling standard. Second, gridded spatial fields of PM<sub>2.5</sub> concentrations are projected using the area-specific percent emission change<sup>14</sup> that corresponds to just meeting the standard at the controlling ambient data site. Additional details on the method are provided in (Kelly et al., 2019a; application of the method to the PM NAAQS risk assessment is described in the remainder of this appendix.

---

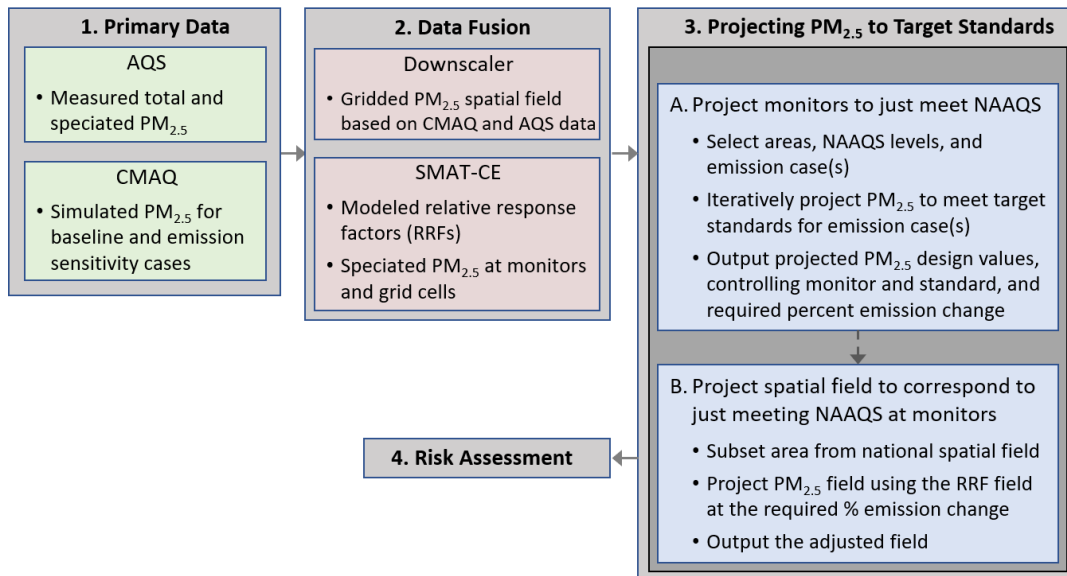

<sup>10</sup> The phrase, "just meeting the PM<sub>2.5</sub> NAAQS" is defined as the conditions where the highest design value (DV) for the controlling standard in the area equals the existing or alternative NAAQS level under consideration. DVs are statistics used in judging attainment of the NAAQS ([www.epa.gov/air-trends/air-quality-design-values](http://www.epa.gov/air-trends/air-quality-design-values)).

<sup>11</sup> [www.epa.gov/aqs](http://www.epa.gov/aqs)

<sup>12</sup> [www.epa.gov/cmaq](http://www.epa.gov/cmaq)

<sup>13</sup> [www.epa.gov/scram/photochemical-modeling-tools](http://www.epa.gov/scram/photochemical-modeling-tools)

<sup>14</sup> Scenarios based on a statistical projection approach were also developed for certain cases as discussed below.

**Figure C-6. Overview of the system for projecting PM<sub>2.5</sub> concentrations to correspond to just meeting NAAQS.** See section C.1.4.6 and Kelly et al., 2019a for more details.

#### C.1.4.2 PM<sub>2.5</sub> Monitoring Data and Area Selection

The 2014-2016 DV period was the most recent period having a complete set of total and speciated PM<sub>2.5</sub> observations available at the time of the study. PM<sub>2.5</sub> concentrations from the 2014-2016 DV period were used in selecting study areas and as the starting point for air quality projections (Figure C-6, Box 1, “AQS”). Total and speciated PM<sub>2.5</sub> concentrations for the 2014-2016 DV period were acquired from AQS. For sites in Los Angeles and Chicago, DVs were invalid during the 2014-2016 period. Los Angeles and Chicago have large populations, recent valid DVs for sites in Los Angeles are above existing standards, and Chicago is part of a CBSA that includes sites with valid 2014-2016 DVs in Indiana. For these reasons, invalid data for sites in these areas were replaced with valid data from other recent periods to enable DVs to be approximated for inclusion in the assessment. Specifically, for sites in Los Angeles and Orange Counties in California, observations from April – October 2014 were replaced with observations from the same months in 2013. For sites in Cook, DuPage, Kane, McHenry, and Will Counties in Illinois, observations from January to mid-July 2014 were replaced with observations from the same months in 2015.

Of the 56 areas initially identified as above the 10/30 selection threshold<sup>15</sup>, DVs for seven areas<sup>16</sup> appeared to meet the threshold due to the influence of wildfires. The influence of

<sup>15</sup> “10/30” indicates an annual standard level of 10 µg/ m<sup>3</sup> and a 24-hr standard level of 3 µg m<sup>-3</sup>

<sup>16</sup> Butte-Silver Bow, MT; Helena, MT; Kalispell, MT; Knoxville, TN; Medford, OR; Missoula, MT; and Yakima, WA

wildfires on DVs for these areas was estimated in part by recalculating 2014-2016 DVs with days removed that were clearly associated with summertime wildfires in the northwest. Since wildfire influence is often excluded when judging NAAQS attainment, these seven areas were excluded from further consideration. Additionally, the Eugene, OR CBSA was excluded. One monitor in the Eugene CBSA has a 24-hr 2014-2016 DV slightly above the 10/30 selection threshold<sup>17</sup>, but the monitor is in a small valley in Oakridge with very local high concentrations of PM<sub>2.5</sub> in winter that are distinct from conditions in the broader CBSA. Finally, the Phoenix-Mesa-Scottsdale, AZ CBSA was excluded. This CBSA had one monitor slightly above the 10/30 DV threshold<sup>18</sup>, but projecting concentrations for the CBSA was judged to be relatively uncertain because the annual DV is invalid at the only site that exceeded the threshold and the 24-hr DV is just above the threshold.

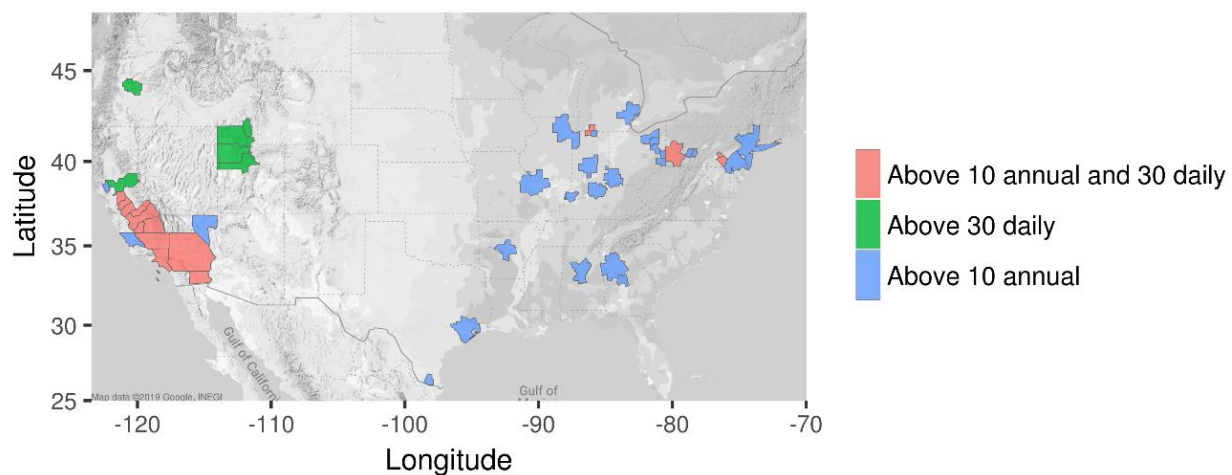

The remaining 47 CBSAs were selected for the risk assessment. These areas are shown in Figure C-7. The maximum 2014-2016 DVs and associated sites for each CBSA are provided in Table C-3, and the counties associated with the CBSAs are listed in Table C-4. DVs were calculated to an extra digit of precision for the air quality projections compared with official DVs. This approach is consistent with DV calculations in previous air quality projections (e.g., USEPA, 2012<sup>19</sup>) and provides a precise target for the iterative projection calculations.

---

<sup>17</sup> The 410392013 monitor in Oakridge has a 24-hr 2014-2016 DV of 31  $\mu\text{g m}^{-3}$

<sup>18</sup> The 040213015 monitor in the Phoenix-Mesa-Scottsdale, AZ CBSA has 24-hr 2014-2016 DV of 31  $\mu\text{g m}^{-3}$

#### **C.1.4.3 Air Quality Modeling**

Air quality modeling was conducted using version 5.2.1 of the CMAQ modeling system (Appel, 2018, Pye et al., 2018) to develop a continuous national field of PM<sub>2.5</sub> concentrations and estimates of how concentrations would respond to changes in PM<sub>2.5</sub> and PM<sub>2.5</sub> precursor emissions (Figure C-6, “CMAQ”). The CMAQ modeling domain (Figure C-9) covered the contiguous U.S. with 12 km horizontal resolution and 35 vertical layers. Since 2015 was the

most recent modeling platform available at the time of the study and represents the central year of the 2014-2016 DV period, 2015 was selected as the baseline modeling year for the PM<sub>2.5</sub> projections. A single modeling year was used due to the time and resources needed to conduct photochemical grid modeling, and because model inputs for the 2016 period were not available at the time of the study.

Information on the CMAQ model configuration for the 2015 modeling is provided in Table C-5. The 2015 model simulation and its evaluation against network measurements of speciated and total PM<sub>2.5</sub> has been described in detail previously (Kelly et al., 2019b). Model performance statistics for PM<sub>2.5</sub> organic carbon, sulfate, and nitrate were generally similar to or improved compared to the performance for other recent national 12 km model simulations. One exception to the generally good model performance was identified for the Northwest region (OR, WA, and ID). Model performance statistics for this region were generally not as good as in our recent modeling due to issues related to unusually high fire influences in 2015, atmospheric mixing over sites near the Puget Sound, and other factors. However, model performance issues in the Northwest have minimal influence on the risk assessment, because only two of the 47 CBSAs are in the Northwest region (i.e., Prineville, OR and part of the Logan, UT-ID, CBSA). Also, the analysis uses ratios of model predictions rather than absolute modeled concentrations, and systematic biases associated with mixing height and fire impact estimates may largely cancel in the ratios. Moreover, fusion of monitor data with model predictions in developing PM<sub>2.5</sub> RRFs and the baseline concentration field helps mitigate the influence of biases in model predictions (as discussed below). Overall, the model performance evaluation (Kelly et al., 2019b) indicates that the 2015 CMAQ simulation provides concentration estimates that are generally as good or better than in other recent applications and are reliable for use in projecting PM<sub>2.5</sub> in the risk assessment. Model performance statistics for PM<sub>2.5</sub> by U.S. climate region and season are provided in Table C-6 and statistic definitions can be found in Table C-7.

**Table C-7. Definition of statistics used in the CMAQ model performance evaluation.**

Statistic	Description
$MB (\mu g\ m^{-3}) = \frac{1}{n} \sum_{i=1}^n (P_i - O_i)$	Mean bias (MB) is defined as the average difference between predicted (P) and observed (O) concentrations for the total number of samples (n)
$RMSE (\mu g\ m^{-3}) = \sqrt{\sum_{i=1}^n (P_i - O_i)^2 / n}$	Root mean-squared error (RMSE)
$NMB (\%) = \frac{\sum_{i=1}^n (P_i - O_i)}{\sum_{i=1}^n O_i} \times 100$	The normalized mean bias (NMB) is defined as the sum of the difference between predictions and observations divided by the sum of observed values
$NME (\%) = \frac{\sum_{i=1}^n  P_i - O_i }{\sum_{i=1}^n O_i} \times 100$	Normalized mean error (NME) is defined as the sum of the absolute value of the difference between predictions and observations divided by the sum of observed values
$r = \frac{\sum_{i=1}^n (P_i - \bar{P})(O_i - \bar{O})}{\sqrt{\sum_{i=1}^n (P_i - \bar{P})^2} \sqrt{\sum_{i=1}^n (O_i - \bar{O})^2}}$	Pearson correlation coefficient

**Figure C-10. U.S. climate regions<sup>22</sup> used in the CMAQ model performance evaluation.**

In addition to the national model performance evaluation just described, CMAQ predictions of PM<sub>2.5</sub> concentrations were evaluated specifically for the CBSAs considered in the risk assessment. In Table C-8, model performance statistics are provided for predictions at monitors in the 47 CBSAs in 2015. Predictions generally agree well with observations over the full set of areas, with NMBs less than 10% in all seasons except Fall (NMB: 23.6%) and correlation coefficients greater than 0.60 in all seasons except Summer (r: 0.56). Model predictions are compared with observations by CBSA in Figure C-11, and NMBs at individual sites in the CBSAs are shown in Figure C-12. Predictions generally agree well with observations in the individual CBSAs, although underpredictions occurred in the Chicago-Naperville-Elgin

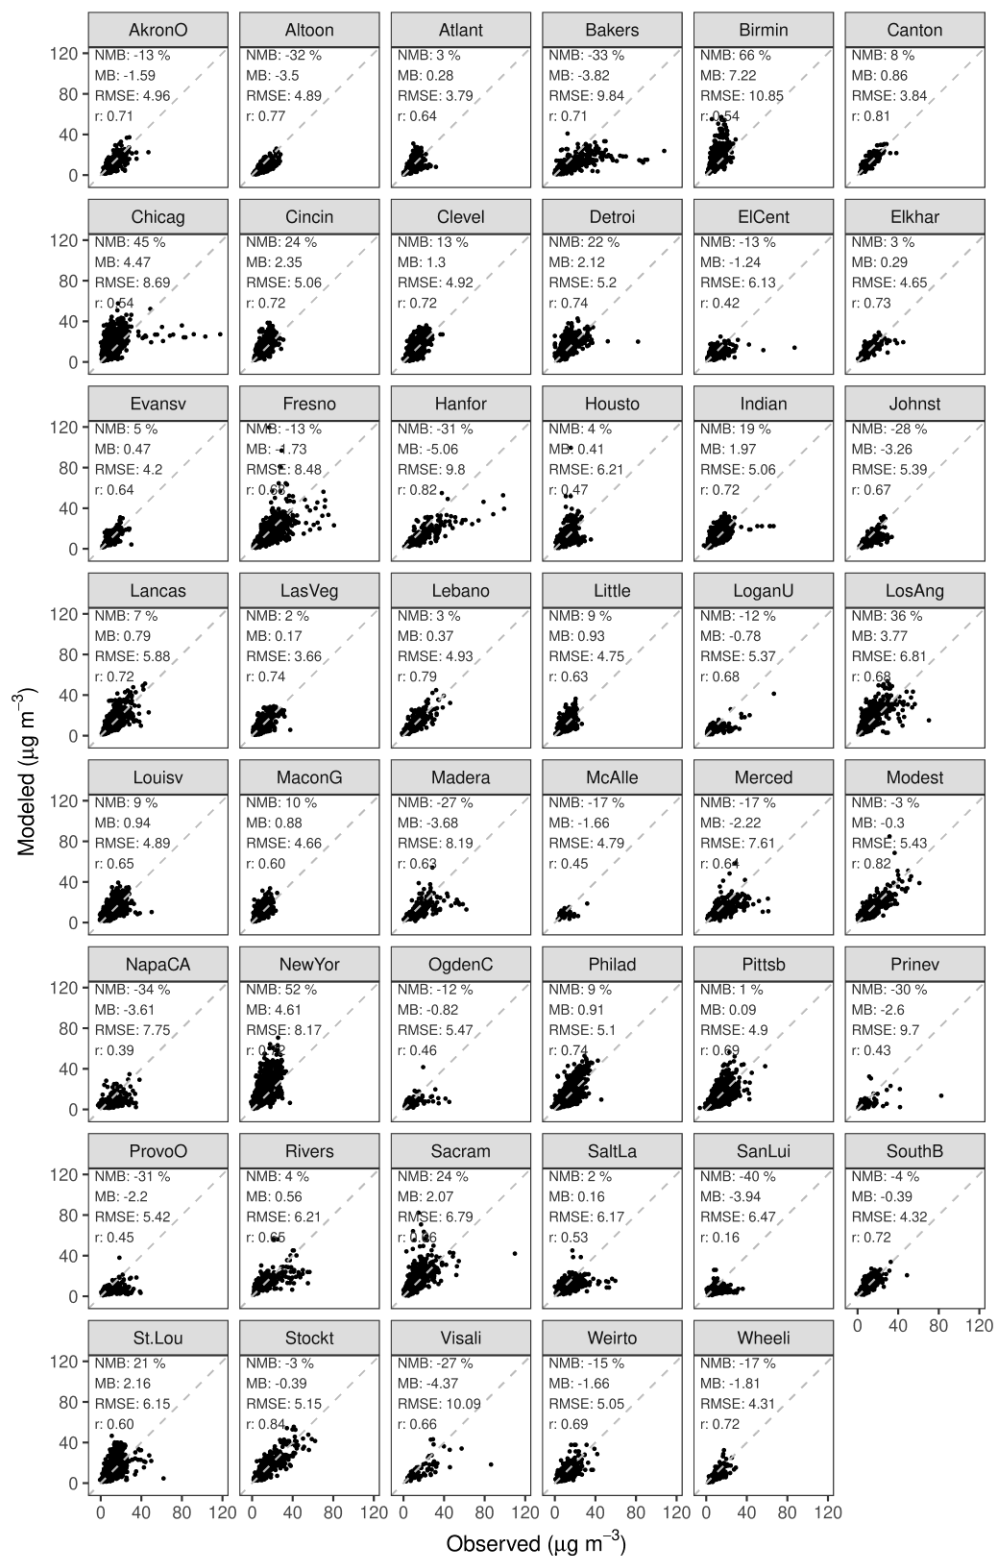

<sup>22</sup> <https://www.ncdc.noaa.gov/monitoring-references/maps/us-climate-regions.php>

CBSA when observed  $\text{PM}_{2.5}$  concentrations were  $> 40 \mu\text{g m}^{-3}$ . The high observed values in Chicago were associated with the 4<sup>th</sup> of July holiday, and the underpredictions on July 4<sup>th</sup> and 5<sup>th</sup> have small influence on the annual  $\text{PM}_{2.5}$  projections in the risk assessment. The NMB is highest for model predictions in the Birmingham-Hoover CBSA (NMB: 66%). As mentioned above, the effects of model bias are mitigated in part by use of relative response factors (i.e., the ratio model predictions from a base and emission control simulation is used in projecting  $\text{PM}_{2.5}$  concentrations, and some model bias likely cancels in the ratio). For the risk assessment projections, the key aspect of the CMAQ modeling is the spatial pattern of  $\text{PM}_{2.5}$  response to changes in emissions. The spatial response pattern was examined in the 47 CBSAs and found to be reasonable even in areas with relatively high bias, such as Birmingham. In Figure C-13, the spatial response pattern associated with the 10/30 projection case for the Birmingham-Hoover CBSA is compared for the proportional projection method and the primary PM projection case based on CMAQ modeling. Relatively high  $\text{PM}_{2.5}$  responsiveness occurred in the urban part of Birmingham and along arterial roads in the CMAQ-based approach. This spatial pattern is consistent with the location of  $\text{PM}_{2.5}$  emission sources in Birmingham and provides a realistic spatial response pattern despite the relatively high bias in the concentration predictions. Overall, both the national model performance evaluation and the evaluation for the 47 CBSAs of the risk assessment support use of the CMAQ modeling in this application.

To inform  $\text{PM}_{2.5}$  projections, annual CMAQ modeling was conducted using the same configuration and inputs as the 2015 base case simulation but with anthropogenic emissions of primary  $\text{PM}_{2.5}$  or  $\text{NOx}$  and  $\text{SO}_2$  scaled by fixed percentages. Specifically, seven simulations were conducted with changes in anthropogenic  $\text{NOx}$  and  $\text{SO}_2$  emissions (i.e., combined  $\text{NOx}$  and  $\text{SO}_2$ , not separate  $\text{NOx}$  and  $\text{SO}_2$  simulations) of -100%, -75%, -50%, -25%, +25%, +50%, and +75%. Two simulations were conducted with changes in anthropogenic  $\text{PM}_{2.5}$  emissions of -50% and +50%. The sensitivity simulations were based on emission changes applied to all anthropogenic sources throughout the year. These “across-the-board” emission changes facilitate projecting the baseline concentrations to just meet a relatively wide range of standards in areas throughout the U.S. using a feasible number of national sensitivity simulations.

**Table C-8. Performance statistics for CMAQ predictions at monitoring sites in the 47 CBSAs considered in the risk assessment.**

Season	Average Observed ( $\mu\text{g m}^{-3}$ )	Average Modeled ( $\mu\text{g m}^{-3}$ )	MB ( $\mu\text{g m}^{-3}$ )	NMB (%)	RMSE ( $\mu\text{g m}^{-3}$ )	NME (%)	<i>r</i>
Winter	12.40	13.45	1.05	8.5	8.03	42.4	0.61
Spring	9.17	9.94	0.77	8.4	5.15	38.6	0.62
Summer	10.35	10.08	-0.27	-2.6	5.51	34.6	0.56

**Figure C-11. Comparison of CMAQ predictions and observations at monitoring sites in the 47 CBSAs considered in the risk assessment.**

**Figure C-12. NMB for CMAQ PM<sub>2.5</sub> predictions at monitoring sites in the 47 CBSAs by season in 2015.**

**Figure C-13. Percent change in 2015 annual average PM<sub>2.5</sub> over the Birmingham CBSA associated with projecting 2014–2016 DVs at monitors to just meet an alternative NAAQS of 10/30 using the proportional projection method and the primary PM<sub>2.5</sub>, CMAQ-based projection method.**

The two emission sensitivity scenarios (primary PM<sub>2.5</sub> and NO<sub>x</sub> and SO<sub>2</sub>) were selected to span a wide range of possible PM<sub>2.5</sub> spatial response patterns. NO<sub>x</sub> and SO<sub>2</sub> emission changes influence concentrations of ammonium nitrate and ammonium sulfate, which are secondary pollutants that often have broad spatial distributions. Primary PM<sub>2.5</sub> emission changes have the greatest influence on PM<sub>2.5</sub> concentrations close to emission sources. The two distinctly different PM<sub>2.5</sub> response patterns for primary PM<sub>2.5</sub> and NO<sub>x</sub> and SO<sub>2</sub> emission changes enable PM<sub>2.5</sub> to be projected for a wide range of conditions. Projecting PM<sub>2.5</sub> for a wide range of conditions is desirable in this study because many PM<sub>2.5</sub> spatial response patterns can cause PM<sub>2.5</sub> concentrations to just meet NAAQS.

#### C.1.4.4 Relative Response Factors for PM<sub>2.5</sub> Projection

The 2015 base case and sensitivity modeling results were used to develop RRFs for projecting PM<sub>2.5</sub> concentrations to correspond to just meeting NAAQS (Figure C-6, Box 2, “SMAT-CE”). Baseline PM<sub>2.5</sub> concentrations are projected by multiplication with RRFs. The RRF for a PM<sub>2.5</sub> species is calculated as the ratio of the concentration in the sensitivity simulation to that in the base case:

$$RRF_{species} = \frac{C_{sensitivity,species}}{C_{base,species}} \quad (1)$$

where  $C_{sensitivity,species}$  is the concentration of the PM<sub>2.5</sub> species in the sensitivity simulation, and  $C_{base,species}$  is the concentration of the PM<sub>2.5</sub> species in the base case simulation. RRFs were calculated for each monitor, grid cell, calendar quarter, standard (annual or 24-hr), species, and sensitivity simulation using SMAT-CE version 1.2.1. RRFs are used in projecting air quality to help mitigate the influence of systematic biases in model predictions (National Resources Council, U.S. EPA, 2018a). More details on the RRF projection method are provided in EPA’s modeling guidance document (U.S. EPA, 2018a) and the user’s guide for the predecessor to the SMAT-CE software (Abt Associates, 2014).

To apply the RRF approach for the risk assessment projections, RRFs for total PM<sub>2.5</sub> were calculated from RRFs for the individual PM<sub>2.5</sub> species using observation-based estimates of PM<sub>2.5</sub> species concentrations in SMAT-CE output. Specifically, total PM<sub>2.5</sub> RRFs ( $RRF_{Tot,PM2.5}$ ) were calculated as the weighted average of the speciated RRFs using the observation-based species concentrations ( $C_{species}$ ) as weights:

$$RRF_{Tot,PM2.5} = \frac{\sum RRF_{species} C_{species}}{\sum C_{species}} \quad (2)$$

Total PM<sub>2.5</sub> RRFs were used to project base-case PM<sub>2.5</sub> concentrations as follows:

$$PM_{2.5,projected} = RRF_{Tot,PM2.5} PM_{2.5,base} \quad (3)$$

The species concentrations used in calculating the total PM<sub>2.5</sub> RRFs were generally based on application of the Sulfate, Adjusted Nitrate, Derived Water, Inferred Carbonaceous material balance approach (SANDWICH) (Frank, 2006) to measurements of PM<sub>2.5</sub> species

concentrations from the Chemical Speciation Network (CSN)<sup>23</sup> and the Interagency Monitoring of Protected Visual Environments (IMPROVE)<sup>24</sup> network. The SANDWICH method corrects for different artifacts in the measurements for PM<sub>2.5</sub> species and total PM<sub>2.5</sub>. An alternative approach to calculating total PM<sub>2.5</sub> RRFs was applied for monitors and grid cells in California due to factors including missing data at the Bakersfield speciation monitor<sup>25</sup> throughout 2014 and part of 2015. For projections in California, RRFs were calculated directly from the ratio of CMAQ PM<sub>2.5</sub> concentration predictions in the sensitivity simulation to the base simulation.

By default, PM<sub>2.5</sub> RRFs for the annual standard are calculated using average concentrations over all modeled days in the quarter, and RRFs for the 24-hr standard are calculated using average concentrations over days with the top 10% of modeled PM<sub>2.5</sub> concentration in the quarter. The default approach was generally followed here, with exceptions for counties in the San Joaquin Valley (SJV) of California and Utah. In these counties<sup>26</sup>, the average concentration over all days in the quarter was used to calculate RRFs for both the 24-hr and annual standards for sites with valid 24-hr and annual DVs. This approach was used to provide stability in projections of annual fields due the variability in the 24-hr and annual RRFs<sup>27</sup>. Also, RRFs were set to one<sup>28</sup> in the third quarter (July-September) for select counties in the San Joaquin Valley and Utah<sup>29</sup> to better reflect the seasonal nature of PM<sub>2.5</sub> in these areas (i.e., PM<sub>2.5</sub> concentrations are relatively high in winter).

RRFs were calculated for each combination of emission sensitivity simulation and the 2015 base case. RRFs corresponding to the percent change in emissions for each sensitivity simulation were then interpolated across the range of emission changes from -100 to +100% to facilitate iterative projections of PM<sub>2.5</sub> concentrations to the nearest percent emission change. PM<sub>2.5</sub> RRFs are shown in Figure C-14 and Figure C-15 as a function of changes in anthropogenic primary PM<sub>2.5</sub> and NO<sub>x</sub> and SO<sub>2</sub> emissions for monitors in the U.S. during the first and third

<sup>24</sup> <http://vista.cira.colostate.edu/Improve/>

<sup>25</sup> Site identification number: 060290014

<sup>26</sup> SJV counties: Fresno, Stanislaus, Kern, Merced, Madera, Tulare, San Joaquin, and Kings; Utah counties: Cache, Box Elder, Davis, Morgan, Weber, Juab, Utah, Salt Lake, and Tooele.

<sup>27</sup> This variability is less of an issue in regional modeling applications where emission changes can be targeted to time periods of elevated PM<sub>2.5</sub> concentrations in the area.

<sup>28</sup> When the RRF is 1, the projected concentration equals the base concentration (Equation 3).

<sup>29</sup> SJV counties: Fresno, Stanislaus, Kern, Merced, and Madera; Utah counties: Cache, Box Elder, Davis, Morgan, Weber, Juab, Utah, Salt Lake, and Tooele. This approach was not applied for Kings, Tulare, and San Joaquin counties in SJV because the percent exceedance of the annual standard was within 10% of the exceedance of the 24-hr standard suggesting that relatively uniform PM<sub>2.5</sub> concentrations occur throughout the year compared with the other SJV counties.

calendar quarters. Spatial fields of  $\text{PM}_{2.5}$  RRFs for 50% reductions in anthropogenic primary  $\text{PM}_{2.5}$  and  $\text{NO}_x$  and  $\text{SO}_2$  emissions are shown in Figure C-16.

**Figure C-14. Annual standard  $\text{PM}_{2.5}$  RRFs for quarters 1 and 3 as a function of the percent change in anthropogenic primary  $\text{PM}_{2.5}$  emissions for monitoring sites in the contiguous U.S.**

**Figure C-15. Annual standard  $\text{PM}_{2.5}$  RRFs for quarters 1 and 3 as a function of the percent change in anthropogenic  $\text{NO}_x$  and  $\text{SO}_2$  emissions for monitoring sites in the contiguous U.S.**

**Figure C-16. Annual average PM<sub>2.5</sub> RRFs at CMAQ grid-cell centers for 50% reductions in anthropogenic (a) NO<sub>x</sub> and SO<sub>2</sub> and (b) primary PM<sub>2.5</sub> emissions.**

#### **C.1.4.5 2015 PM<sub>2.5</sub> Concentration Fields**

To develop a baseline gridded PM<sub>2.5</sub> concentration field for projection with PM<sub>2.5</sub> RRFs, a Bayesian statistical model (i.e., Downscaler) was applied (Figure C-6, Box 2, “Downscaler”) (Berrocal et al., 2012). Downscaler makes predictions of PM<sub>2.5</sub> concentrations to a spatial field of receptor points using PM<sub>2.5</sub> monitoring data and CMAQ model predictions as inputs. Downscaler takes advantage of the accuracy of the monitoring data and the spatial coverage of the CMAQ predictions to develop new predictions of PM<sub>2.5</sub> concentration over the U.S.

The Downscaler model is routinely applied by U.S. EPA to predict 24-hr average PM<sub>2.5</sub> concentrations at the centroids of census tracts in the contiguous U.S. (U.S. EPA, 2018b). The model configuration used here is generally consistent with the previous applications, but here predictions were made to the centers of the CMAQ model grid cells rather than to census-tract centroids. Also, PM<sub>2.5</sub> measurements from the IMPROVE monitoring network were used in addition to measurements included in the AQS database. 24-hr average PM<sub>2.5</sub> concentrations were predicted for the 2015 period, and the 24-hr PM<sub>2.5</sub> fields were averaged to the quarterly periods of the PM<sub>2.5</sub> RRFs for use in projection.

Annual average PM<sub>2.5</sub> concentrations from the monitoring network and CMAQ simulation that were used in model fitting are shown in Figure C-17 along with the resulting Downscaler predictions. Cross-validation statistics are provided in Table C-9 based on comparisons of Downscaler predictions against the 10% of the observations that were randomly withheld from model fitting.

**Figure C-17. Annual average of the 2015 PM<sub>2.5</sub> observations and CMAQ predictions used in the Downscaler model, and the annual average of the Downscaler PM<sub>2.5</sub> predictions.**

**Table C-9. Cross-validation statistics associated with the 2015 Downscaler predictions.**

Number of Monitors	Mean Bias <sup>a</sup> ( $\mu\text{g m}^{-3}$ )	Root Mean Squared Error <sup>b</sup> ( $\mu\text{g m}^{-3}$ )	Mean Coverage <sup>c</sup>
1101	0.37	3.17	0.95
<sup>a</sup> The mean of all biases across the CV cases, where the bias of each prediction is the downscaler prediction minus the observed value. <sup>b</sup> The bias is squared for each CV prediction, then the square root of the mean of all squared biases across all CV predictions is obtained. <sup>c</sup> A value of 1 is assigned if the measured value lies in the 95 <sup>th</sup> percentile CI of the Downscaler prediction (the Downscaler prediction $\pm$ the Downscaler standard error), and 0 otherwise. This column is the mean of all those 0's and 1's.			

#### C.1.4.6 Projecting PM<sub>2.5</sub> to Just Meet the Standards

PM<sub>2.5</sub> was projected from baseline concentrations to levels corresponding to just meeting NAAQS using the monitoring data (section C.1.4.2), RRFs (section C.1.4.4), and baseline concentration fields (section C.1.4.5) described above. The projection was done in two steps as shown in Box 3 of Figure C-6. Projections were performed for the existing (12/35)<sup>30</sup> and alternative (10/30)<sup>31</sup> standards.

First, monitors in the CBSA of interest were identified, and concentrations from these monitors were subset from the national monitoring dataset. The measured concentrations were then projected using the corresponding PM<sub>2.5</sub> RRF. PM<sub>2.5</sub> DVs were calculated using the projected concentrations, and the difference between the maximum projected DV and target standard was determined. DV projections over the complete range of percent emission changes (-100 to 100%) were performed using bisection iteration until the difference between the

<sup>30</sup> Annual standard level of 12  $\mu\text{g m}^{-3}$  and 24-hr standard level of 35  $\mu\text{g m}^{-3}$

<sup>31</sup> Annual standard level of 10  $\mu\text{g m}^{-3}$  and 24-hr standard level of 30  $\mu\text{g m}^{-3}$

maximum projected DV in the CBSA and the standard level was zero or within the difference associated with a 1% emission change. Iterative projections of annual and 24-hr DVs were performed separately, and the controlling standard was determined as the standard requiring the greater percent emission change<sup>32</sup>. In cases where the emission change needed to just meet the target annual or 24-hr standard was outside of the  $\pm 100\%$  range, the standard could not be met using the modeled air quality scenarios. If neither the annual nor 24-hr standard could be just met with emission changes within  $\pm 100\%$ , then an alternative projection approach was used (discussed below).

Second, 2015 PM<sub>2.5</sub> concentration fields developed with Downscaler were projected according to the percent emission change required for the maximum projected DV to just meet the controlling standard. The projection was done by multiplying the gridded spatial fields of quarterly average PM<sub>2.5</sub> concentrations based on Downscaler modeling with the gridded spatial fields of quarterly PM<sub>2.5</sub> RRFs corresponding to the percent emission change required to just meet the controlling standard. The projected fields of quarterly average PM<sub>2.5</sub> concentrations were then averaged to produce the annual average projected field.

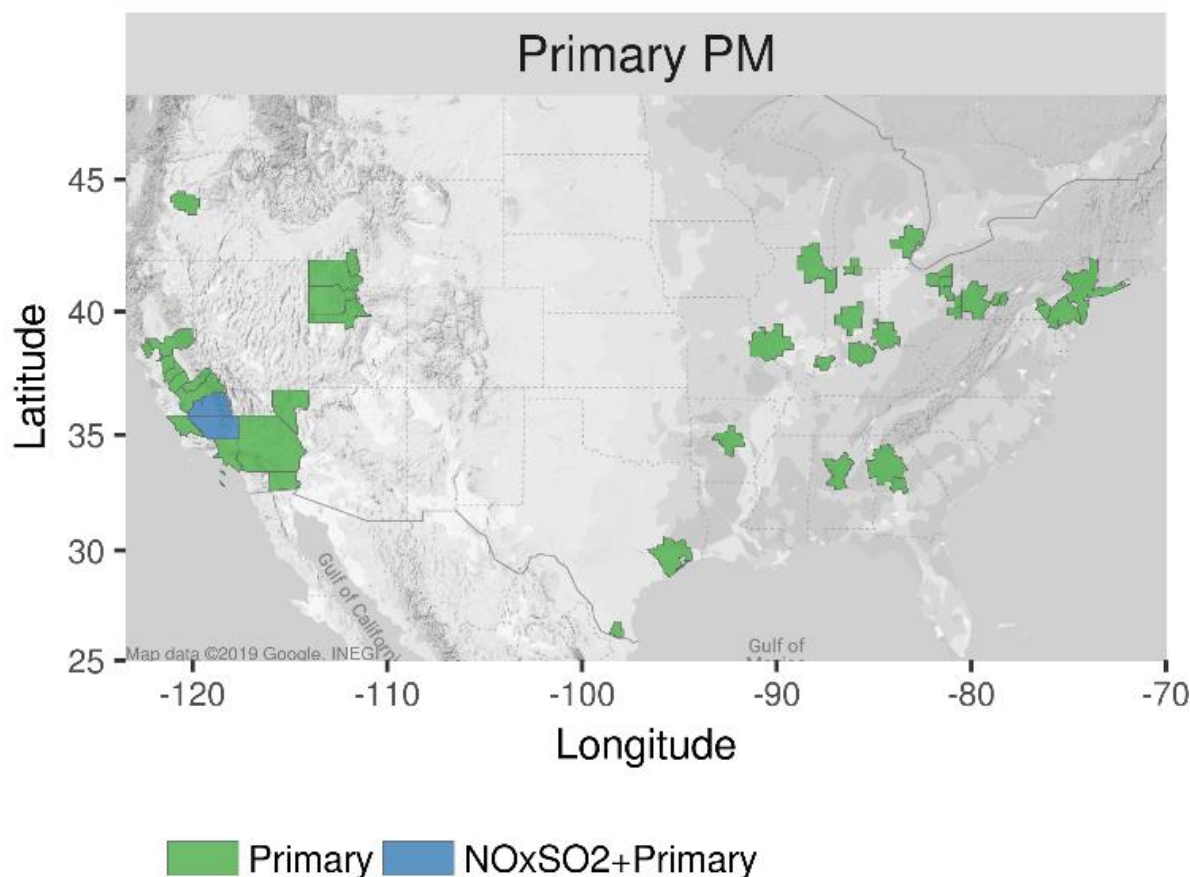

Since PM<sub>2.5</sub> concentrations can be projected in multiple ways to just meet a standard, projections were done for two scenarios that provide results for a range of PM<sub>2.5</sub> conditions. The first scenario is referred to as “Primary PM” or Pri-PM because projections were largely based on RRFs developed using CMAQ sensitivity simulations with primary PM<sub>2.5</sub> emission changes. For three CBSAs<sup>33</sup>, standards could not be met using primary PM<sub>2.5</sub> emission reductions alone. PM<sub>2.5</sub> concentrations were projected for these areas using a combination of primary PM<sub>2.5</sub> and NO<sub>x</sub> and SO<sub>2</sub> emission reductions in the Primary PM scenario<sup>34</sup> (Figure C-18).

---

<sup>32</sup> Note that calculations are performed in terms of percent emission reduction. Therefore, in cases where DVs are projected to just meet standards greater than the baseline DVs, the required percent emission reduction is negative (i.e., an emission increase is required), and the smaller absolute percent emission change is selected as the controlling case. For example, the annual standard would be selected as controlling in a case where a 10% emission increase is needed to meet the annual standard and a 50% emission increase is needed to meet the 24-hr standard (because -10 is greater than -50).

<sup>33</sup> Bakersfield, Hanford-Corcoran, and Visalia-Porterville (all in California)

<sup>34</sup> This approach was applied by using RRFs from the NO<sub>x</sub> and SO<sub>2</sub> emission sensitivity simulations to eliminate a fraction of the difference between the maximum base DV and the standard level and then using RRFs from the primary PM<sub>2.5</sub> emission sensitivity simulations to eliminate the remainder of the difference. The fraction of the difference eliminated with NO<sub>x</sub> and SO<sub>2</sub> emission reductions was as follows: 0.4 for Bakersfield, 0.5 for Visalia-Porterville, and 0.6 for Hanford-Corcoran

**Figure C-18. Projection method used for each CBSA in the “Primary PM” projection case.**  
See text for details.

The second scenario is referred to as “Secondary PM” or Sec-PM because projections were largely based on RRFs developed using CMAQ modeling with NO<sub>x</sub> and SO<sub>2</sub> emission changes, which affect concentrations of secondary PM components such as ammonium nitrate and ammonium sulfate. For 22 CBSAs<sup>35</sup>, standards could not be just met using NO<sub>x</sub> and SO<sub>2</sub> emission changes alone. These areas were projected using the proportional scaling method<sup>36</sup> (Figure C-19). The proportional method was selected to gap-fill the Secondary PM case because

<sup>35</sup> Altoona, PA; Atlanta-Sandy Springs-Roswell, GA; Bakersfield, CA; Chicago-Naperville-Elgin, IL-IN-WI; El Centro, CA; Elkhart-Goshen, IN; Fresno, CA; Hanford-Corcoran, CA; Las Vegas-Henderson-Paradise, NV; Los Angeles-Long Beach-Anaheim, CA; Macon, GA; Madera, CA; McAllen-Edinburg-Mission, TX; Modesto, CA; Napa, CA; New York-Newark-Jersey City, NY-NJ-PA; Prineville, OR; Riverside-San Bernardino-Ontario, CA; St. Louis, MO-IL; San Luis Obispo-Paso Robles-Arroyo Grande, CA; Visalia-Porterville, CA; Wheeling, WV-OH

<sup>36</sup> In the proportional method, the spatial field is uniformly scaled by a fixed percentage that corresponds to the percent difference between the controlling standard level and maximum PM<sub>2.5</sub> DV for the controlling standard. The controlling standard (annual or 24-hr) is identified as the one with the greater percent difference between the maximum DV and the standard level.

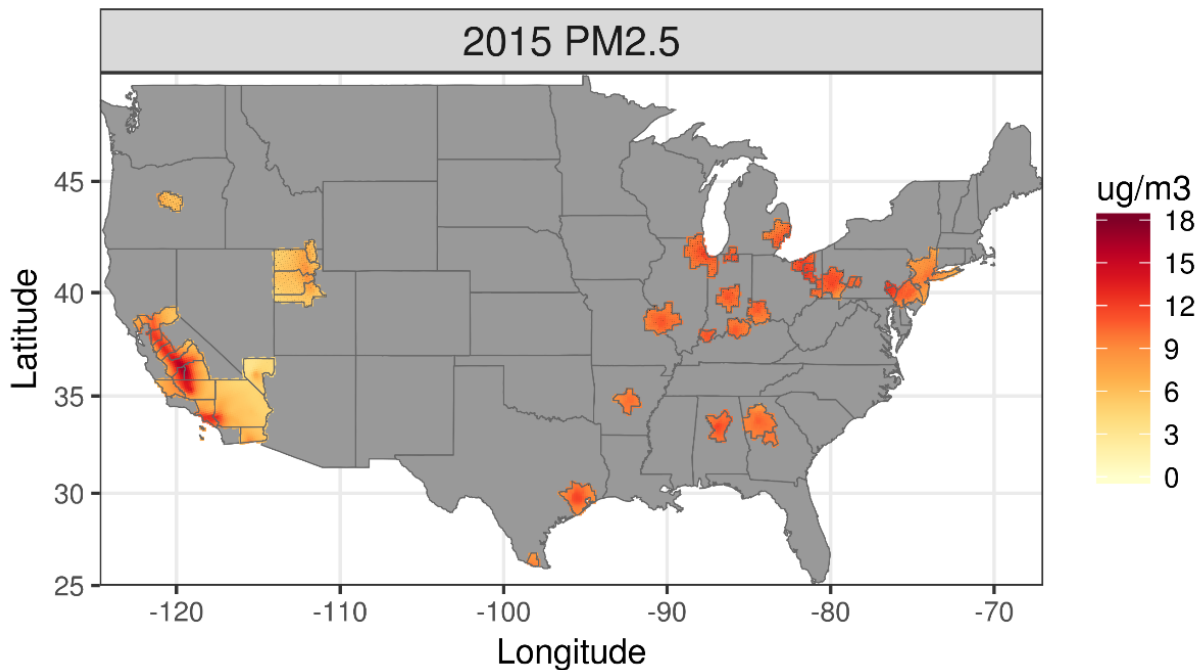

it is based on a spatially uniform percent change in  $PM_{2.5}$  over the area that is like the conceptually broad spatial response pattern of  $PM_{2.5}$  to changes in secondary  $PM_{2.5}$  components. The proportional method has been used previously in the Risk and Exposure Assessment for the 2012 PM NAAQS review (U.S. EPA, 2010).

**Figure C-19. Projection method used for each CBSA in the “Secondary PM” projection case.**

The baseline 2015 concentration in the 47 CBSAs is shown in Figure C-20. These concentrations are the same as those in Figure C-17 but are shown only for the CBSAs included in the projections. In Figure C-21, the difference in annual concentration projected for the 12/35 case and the 2015 baseline concentration is shown. The positive and negative differences reflect areas where concentrations were projected to higher and lower levels to just meet the standard, respectively. In Figure C-22, the difference between the annual concentration projected for the 10/30 case and the 2015 baseline concentration. Negative values indicate that concentrations

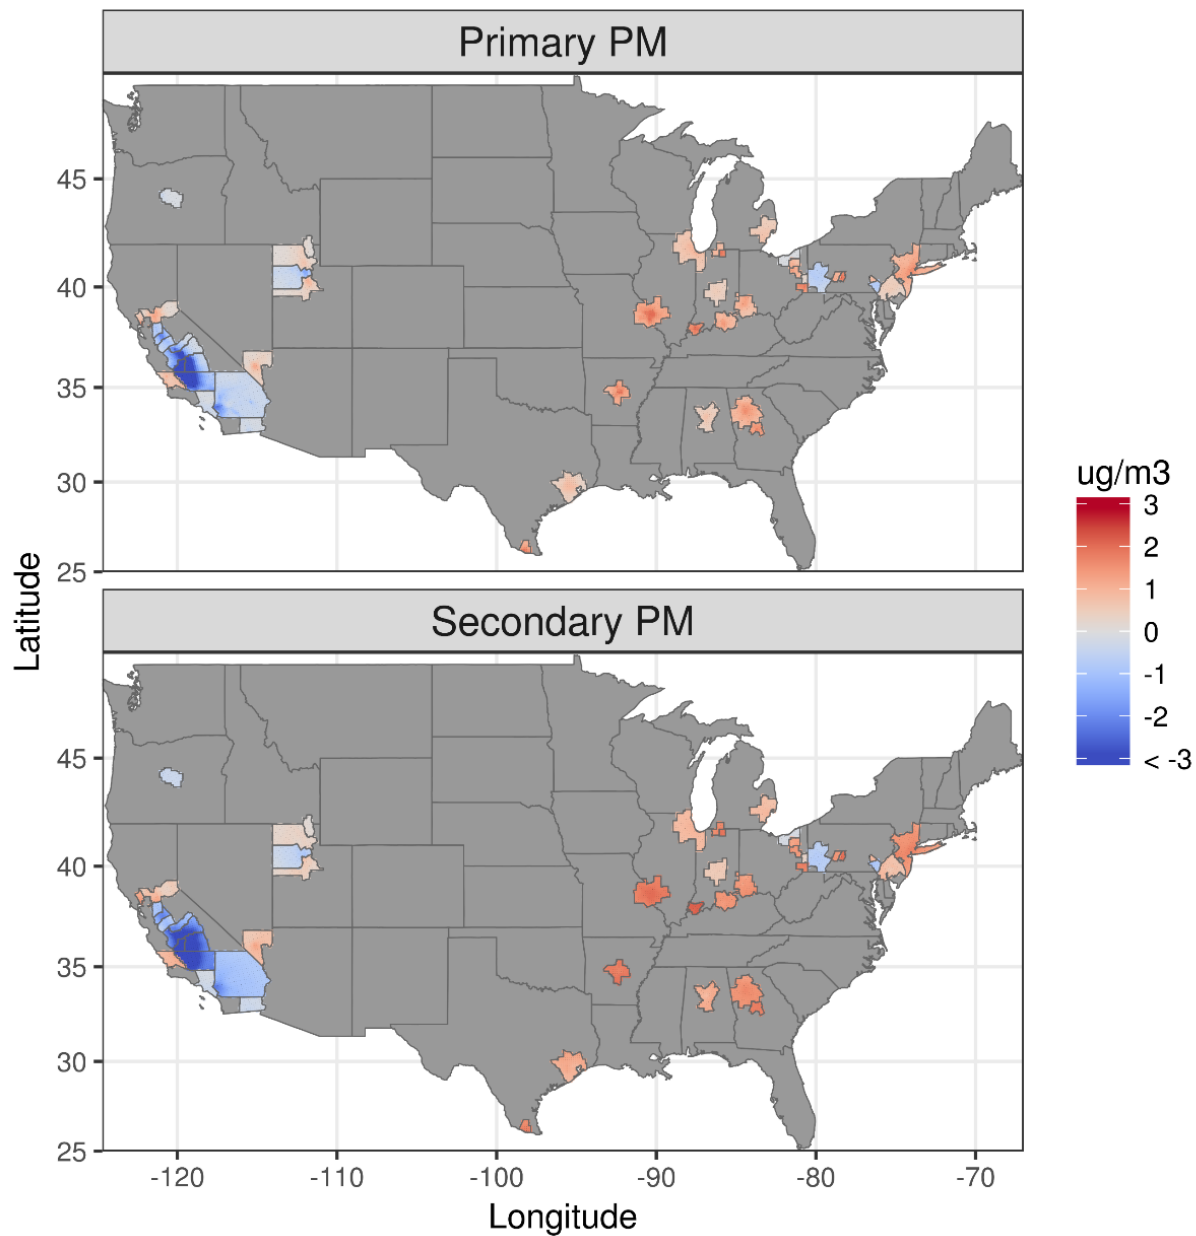

were projected to lower levels in all cases for the areas. The difference in projected concentrations for the 10/30 and 12/35 fields is shown in Figure C-23. Baseline and projected PM<sub>2.5</sub> DVs for monitors in the 47 CBSAs are provided in Table C-33, Table C-34, Table C-35, and Table C-36 in section C.4.<sup>37</sup>

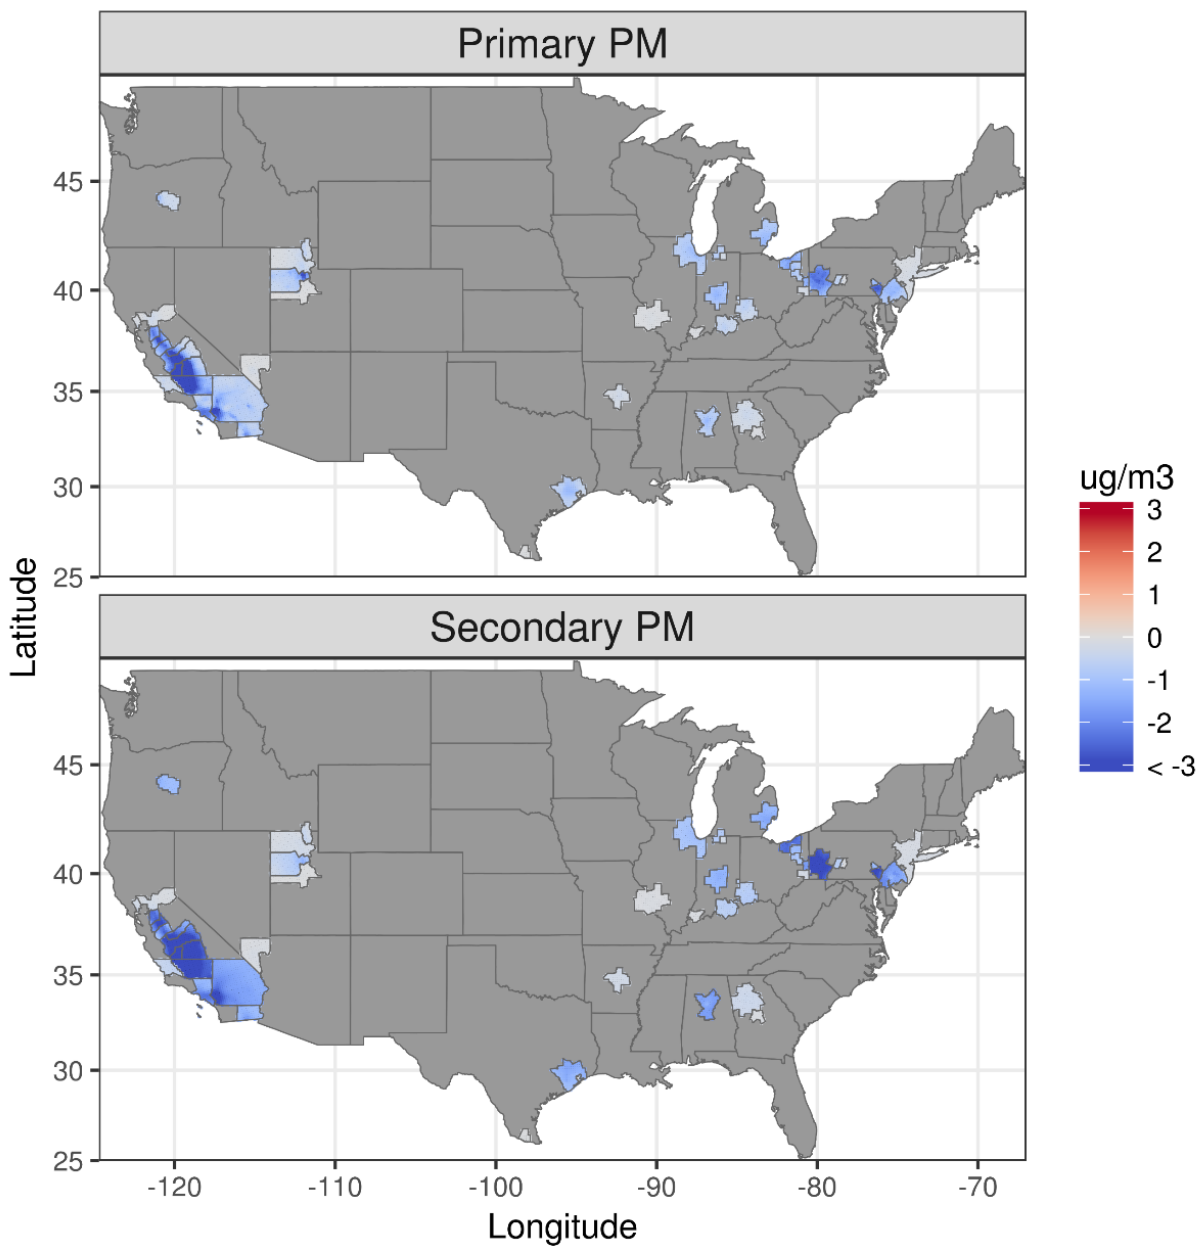

**Figure C-20. Annual average 2015 PM<sub>2.5</sub> concentrations in the 47 CBSAs based on Downscaler modeling.**

<sup>37</sup> The tables report the percent emission reduction associated with just meeting standards in the current modeling. These values should not be interpreted as the percent emission reductions that would be required to meet the standards in other application (e.g., attainment demonstrations for state implementation plans). The modeling done here was designed to quickly project PM<sub>2.5</sub> fields throughout the U.S. with a broad range of model response patterns, rather than to apply model configurations and emission scenarios specific to just meeting standards most efficiently in particular regions.

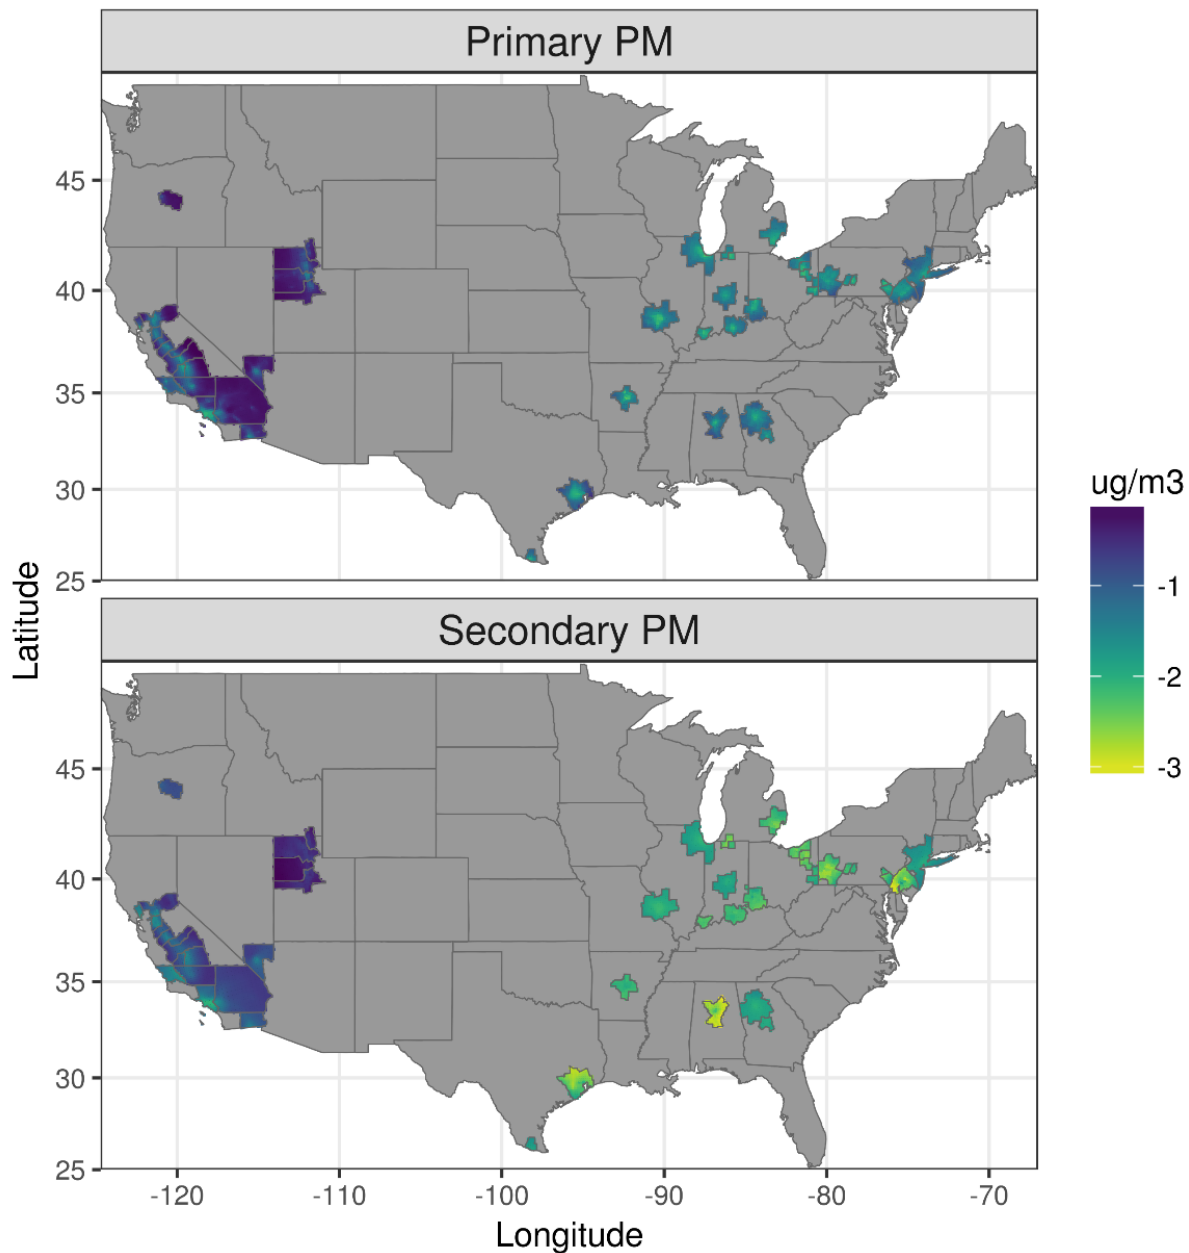

**Figure C-21. Difference between the annual average projected PM<sub>2.5</sub> concentrations and the 2015 baseline concentrations for the 12/35 projection cases (i.e., 12/35 – baseline).**

**Figure C-22. Difference between the annual average projected PM<sub>2.5</sub> concentrations and the 2015 baseline concentrations for the 10/30 projection cases (i.e., 10/30 – baseline).**

**Figure C-23. Difference between the annual average projected PM<sub>2.5</sub> concentrations in the 10/30 and 12/35 cases (i.e., 10/30 – 12/35) for the Primary PM and Secondary PM projection cases.**

#### **C.1.4.7 Limitations**

There are several limitations associated with the air quality projections. First, the baseline and projected concentrations rely on model predictions. Although state-of-the-science modeling methods were applied, and model performance was generally good, there is uncertainty associated with the model predictions. Second, due to the national scale of the assessment, the

modeling scenarios are based on “across-the-board” emission changes in which emissions of primary PM<sub>2.5</sub> or NO<sub>x</sub> and SO<sub>2</sub> from all anthropogenic sources throughout the U.S. are scaled by fixed percentages. Although this approach tends to target the key sources in each area, it does not tailor emission changes to specific periods or sources. More refined emission scenarios could be beneficial for projections in areas with relatively large seasonal and/or spatial variability in PM<sub>2.5</sub>. Similarly, fine scale simulations (e.g., 4 km or less), which are not possible due to the national scale of the assessment, would be beneficial in areas with complex terrain and relatively large spatial gradients in PM<sub>2.5</sub>. A third limitation arises because many emission cases could be applied to project PM<sub>2.5</sub> concentrations to just meet standards. We applied two projection cases that span a wide range of possible conditions, but these cases are necessarily a subset of the full set of possible projection cases.

### **C.1.5 Risk Modeling Approach**

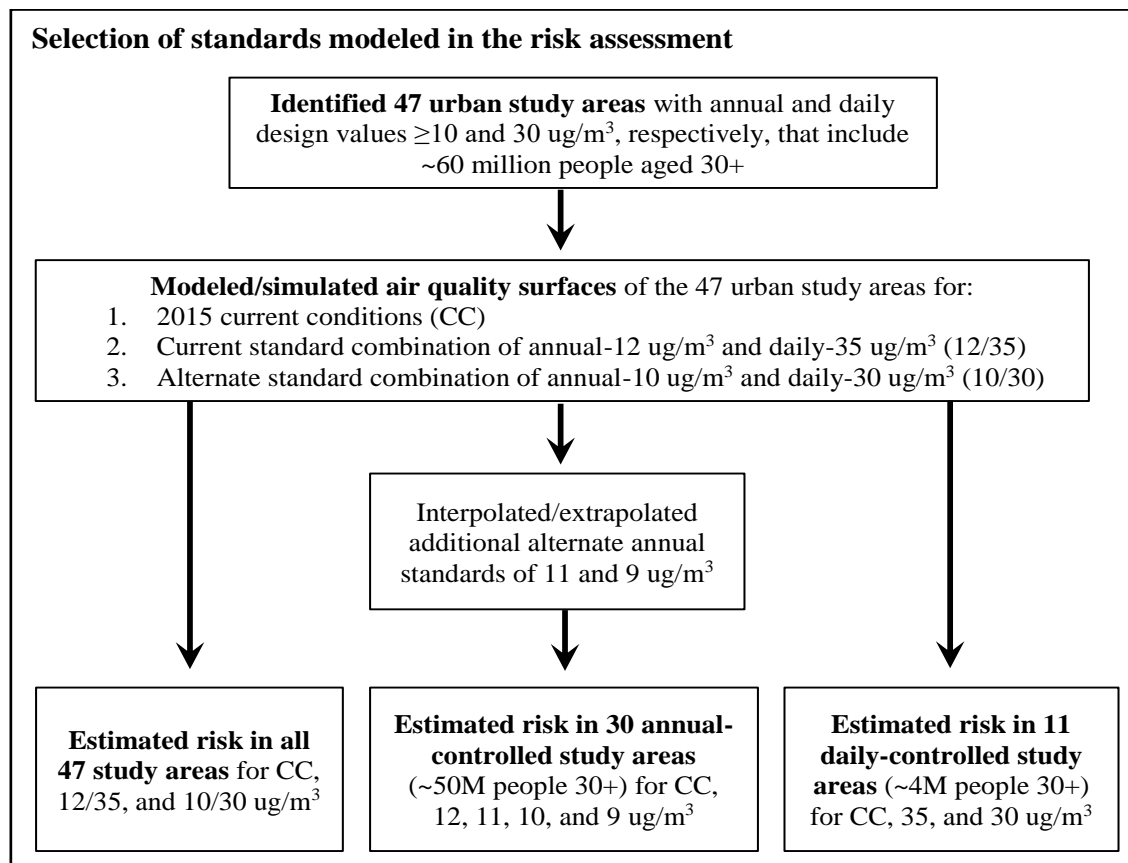

Risk modeling for this assessment was completed using the EPA’s Environmental Benefits Mapping and Analysis Program - Community Edition (BenMAP-CE) version 1.4.14.1.<sup>38</sup> BenMAP-CE was used to estimate risk at the 12 km grid cell level for grid cells intersected by the 47 urban study area CBSAs included in risk modeling. BenMAP-CE is an open-source computer program that calculates the number and economic value of air pollution-related deaths and illnesses. The software incorporates a database that includes many of the concentration-response relationships, population files, and health and economic data needed to quantify these impacts. BenMAP-CE also allows the user to import customized datasets for any of the inputs used in modeling risk. For this analysis, CR functions developed specifically for this assessment were imported into BenMAP-CE (section C.1.1). The BenMAP-CE tool estimates the number of health impacts resulting from changes in air quality—specifically, ground-level ozone and fine particles. BenMAP-CE can also translate these incidence estimates into monetized benefits, although that functionality was not employed for this risk assessment. Inputs to BenMAP-CE used for this risk assessment are identified above in Figure C-1 and described in detail in sections C.1.1, C.1.2, C.1.3, and C.1.4.

An overall flow diagram of the risk assessment approach is provided in Figure C-24. Application of this approach resulted in separate sets of risk estimates being generated for three groupings of urban study areas including: (a) the full set of 47, (b) the 30 areas controlled by the annual standard, and (c) the 11 areas controlled by the 24-hr standard. Risk estimates are presented and discussed for each of these groupings in PA section 3.3.2, with greater emphasis being placed on results generated for the full set of 47 urban study areas and 30 annual-

---

<sup>38</sup> BenMAP-CE is a free program which can be downloaded from: <https://www.epa.gov/benmap>.

controlled study areas given interest in national representation and on those study areas where we could also consider the alternative annual standards of 9 and 11  $\mu\text{g}/\text{m}^3$ .

**Figure C-24. Flow diagram of risk assessment technical approach.**

## C.2 SUPPLEMENTAL RISK RESULTS

As noted earlier, this appendix presents more granular risk information that supplements the aggregated risk estimates presented and discussed in section 3.3.2 of the PA. This supplemental information is intended to provide additional context for the interpretation of summary risk estimates presented in section 3.3.2 above, and includes:

- Modeled risk estimates that underly summary tables presented in PA section 3.3.2 aggregated to the CBSA-level (i.e., the urban study area) (section C.2.1).* Here we begin by presenting the summary table for the full set of 47 study areas followed by the CBSA-level data underlying each summary table. We then present the summary table for the 30-annual-controlled study areas, followed by the CBSA-level data underlying those summary tables.

- *Additional graphics including line plots, maps and scatter plots illustrating the distribution of the grid-level risk estimates (section C.2.2).* These graphics allow the reader to consider different aspects of the grid-level data underlying the summary tables presented in the PA (e.g., spatial distribution of risk across the cities included in the risk assessment, how the distribution of grid-cell level risk estimates shifts as lower alternative standards are considered).

Note that at the end of section C.2 we present key observations from consideration both of the CBSA-level risk estimates presented in section C.2.1 and the graphics illustrating the distribution of grid-level risk estimates in section C.2.2.

### **C.2.1 Risk Summary Tables and Underlying CBSA-Level Risk Estimates**

This section presents the full results of the risk assessment conducted in support of this review of the PM NAAQS. This includes aggregate results for all 47 urban study areas across each of the endpoints modeled, as well as the underlying results for individual cities for each endpoint. The aggregate results are consistent with those reported above in the summary tables in Chapter 3 (section 3.3.2). The more refined results for each urban study area presented below reflect the detailed 12 km grid-level risk estimates aggregated to the CBSA-level (i.e., the urban study area).

The results are organized as follows: the summary tables for the full set of 47 urban study areas, followed by tables of the associated CBSA-level risk estimates, are presented in section C.2.1.1. Then, in section C.2.1.2, we break out the 30 annual-controlled study areas (both in summary form and by the associated CBSA-level risk estimates) to show the results of simulating alternative annual standard levels of  $11.0 \mu\text{g}/\text{m}^3$  and  $9.0 \mu\text{g}/\text{m}^3$ . We do not report the results for the 11 daily-controlled areas separately, as readers can find the CBSA-level results for these areas within the tables presented for the full set of 47 study areas.<sup>39</sup> In reviewing the CBSA-level risk estimates, it is important to consider several details related to these tables including:

- In addition to the information on current and alternative standards presented in PA section 3.3.2, the tables below include information on 2015 current conditions.
- The CBSA tables are organized by health endpoint (i.e., each table presenting risk estimates for a specific endpoint). Then within a given CBSA table, the columns

---

<sup>39</sup> The set of 11 daily-controlled study areas is shown in Figure C-5 and includes the following study areas: Fresno, CA, Logan, UT-ID, Madera, CA, Merced, CA, Modesto, CA, Ogden-Clearfield, UT, Prineville, OR, Provo-Orem, UT, Sacramento-Roseville-Arden-Arcade, CA, Salt Lake City, UT, Visalia-Porterville, CA.

present risk estimates for specific air quality scenarios (e.g., current conditions, current standard and so on) with the rows presenting risks for individual CBSAs. To aid cross-walk comparison between the summary tables and the CBSAs, the order of the standards presented in the CBSA tables matches the order of standards presented in the summary tables.

- Each CBSA table includes a “total” as the last row in the table, which provides the sum for that air quality scenario/health endpoint combination across all study areas. This total value can be used as a cross-check with the matching value presented in the summary table for a particular air quality scenario/health endpoint combination.
- Given the national-scale of the effect estimates used in modeling mortality risks, greater confidence is associated with aggregated (cross-city) risk estimates (as presented in PA section 3.3) than with individual CBSA-level results.

#### **C.2.1.1 CBSA-Level Results for the 47 Urban Study Areas**

Here we begin by presenting the summary tables of absolute risk and risk reduction for the full set of 47 study areas (Table C-10 and Table C-11). Then we provide tables of individual endpoint- and study- specific CBSA-level risk estimates (Table C-12, Table C-13, Table C-14, Table C-15, Table C-16, Table C-17, Table C-18, Table C-19, and Table C-20).

**Table C-10. Absolute risk summary table of the 47 urban study areas, including current conditions (2015).**

### C.2.1.2 CBSA-Level Results for the 30 Annual-Controlled Urban Study Areas

Here we begin by presenting the summary tables of absolute risk and risk reduction for the 30 annual-controlled study areas (Table C-21 and Table C-22) where the annual standard was controlling. Then we provide tables of individual endpoint- and study- specific CBSA-level risk estimates (Table C-23, Table C-24, Table C-25, Table C-26, Table C-27, Table C-28, Table C-29, Table C-30, and Table C-31).

**Table C-21. Absolute risk summary table of the 30 urban study areas, including current conditions (2015).**

Endpoint	Study	Absolute Risk						
		Current Conditions (2015)	Simulation Method*	Current Annual Standard (12 µg/m³)	Alternative Annual Standard (11 µg/m³)	Alternative Annual Standard (10 µg/m³)	Alternative Annual Standard (9 µg/m³)

### **C.2.2 Impact of Alternative Standards on the Distribution of Risk Across Ambient PM<sub>2.5</sub> Levels**

The tables of risk results presented in section C.2.1 illustrate the estimated risk of premature death under current and alternative PM<sub>2.5</sub> standards. As the city-specific results indicate, both total risk and risk reductions estimated to occur under alternative standards can vary substantially by urban area. This is due to differences in underlying demographics (e.g., size and age of population), health status (e.g., underlying death rates) and exposure (air quality conditions). Furthermore, each of these CBSA estimates represents an aggregation of underlying 12 km grid cell results, masking the underlying variability in the distribution of risk under different scenarios. Thus, it can be challenging to understand how patterns of risk are changing under air quality simulated to just meet the current or alternative standards.

To better illustrate the distribution of risk under the current standards, and how that distribution changes under potential alternative standards, this section presents graphics depicting these changes both in aggregate and at the grid-cell level. It would be possible to illustrate these changes separately for each endpoint and CR function, as was done numerically in the tables in section C.2.1. However, because the pattern of risk and risk reduction is similar across endpoints, we have chosen to focus on a single endpoint to illustrate the changes graphically. Consequently, as with the graphics presented in the PA section 3.3.2, the graphics presented in this section are also based on long-term exposure-related IHD mortality modeled using effect estimates obtained from Jerrett et al. (2016). The first set of graphics presented in this section (Figure C-25, Figure C-26, Figure C-27, Figure C-28, and Figure C-29) include results for the full set of 47 urban study areas and the second set (Figure C-30 and Figure C-31) include results for the 30 annual-controlled study areas. These graphical plots include:

- Line graphs showing the distribution of gridded risk estimates across annual-averaged PM<sub>2.5</sub> concentrations (Figure C-25 and Figure C-30). These figures allow the reader to consider how the distribution of risk shifts when simulating air quality that just meets the current standard (12/35 µg/m<sup>3</sup>) relative to 2015 current conditions and subsequently how that distribution of risk shifts downward when simulating air quality that just meets alternative standards of 10/30 µg/m<sup>3</sup>.
- Maps showing the 12 km grid-level risk estimates associated with each of the 47 urban study areas. In these representative maps each grid cell is shown as a square, with the color of the square going from green (lower risk estimates) to red (higher risk estimate) colors. The center of the color scales (the beginning of yellow) has been set to a risk estimate of two premature deaths. This means that green squares represent grid cells where 0-1 premature deaths are estimated,
